Initial management of patients with pericardial tamponade should focus on the typical ABCs of resuscitation (airway, breathing, circulation). Certain caveats should be made, however. Although the primary pathophysiologic abnormality underlying hemodynamic compromise in patients with pericardial tamponade is ventricular filling, the benefit of volume infusion to improve filling is controversial. Animal studies have shown variable results with respect to the hemodynamic benefit of volume infusion, which may improve systemic perfusion only in patients with hypovolemia. Strong supportive data in humans are lacking, however. In patients with traumatic pericardial tamponade, large-volume infusions may actually precipitate further deterioration. Strong evidence supporting specific inotropic agents is lacking as well, although theoretically agents that reduce the elevated vascular resistance, such as dobutamine and milrinone, would seem ideal. Mechanical ventilation should generally be avoided except in patients with respiratory failure; the positive airway pressure associated with mechanical ventilation decreases venous return and cardiac output.
performed via needle aspiration under echocardiographic, CT, or fluoroscopic guidance. In patients who exhibit rapid cardiac decompensation or are in cardiac arrest, the EP should perform emergency pericardiocentesis without waiting for imaging guidance. The procedure is performed with a 16- or 18-gauge needle, most commonly inserted into the left paraxiphoid area of the chest. The needle is pointed downward at an approximately 30-degree angle to the chest to bypass the left costal margin and is aimed toward the left shoulder. The needle should be inserted and advanced slowly until the pericardium is penetrated and fluid is aspirated. Use of a sheathed needle can facilitate the process—once the pericardium has been penetrated, the core of the needle can be removed with the sheath left in the pericardial space to assist in further removal of fluid. Some researchers have advocated attaching ECG leads to the hub of the needle so that when the pericardium is penetrated, an injury pattern (i.e., ST-segment elevation) will be noted. However, a recent review recommends against this practice because of the likelihood of misleading results.

In patients with acute cardiac decompensation, aspiration of even 10 to 20 mL of blood should be sufficient to produce some hemodynamic improvement. However, once full cardiac arrest has occurred, pericardiocentesis has a limited success rate. Potential complications of pericardiocentesis include puncture or laceration of the cardiac chambers, injury to coronary vessels, pneumothorax, ventricular dysrhythmias, pneumopericardium, and delayed infection. These complications are more common in the setting of emergency pericardiocentesis, which is sometimes performed without imaging guidance.

Because pericardiocentesis is less likely to be successful in patients with clotted hemothorax, surgical drainage will be necessary. Surgical drainage is also required in patients in whom intrapericardial bleeding is present (e.g., postoperative pericardial tamponade, traumatic pericardial tamponade, pericardial tamponade with aortic dissection). In these patients, pericardiocentesis is temporizing at best; in conjunction with surgical drainage, definitive repair of the bleeding sites is essential. Additional therapy should focus on treating the underlying cause of the pericardial inflammation that led to pericardial tamponade.

**FOLLOW-UP AND NEXT STEPS IN CARE**

Patients with pericardial tamponade should be admitted to an intensive care setting for definitive therapy and close hemodynamic monitoring. If surgical therapy is indicated, emergency surgical consultation is mandatory. When surgical therapy is not planned, cardiology consultation is most appropriate for the performance of pericardiocentesis under echocardiographic guidance. Nephrology consultation is also appropriate for urgent hemodialysis in patients with uremia.

**MYOCARDITIS**

**PATHOPHYSIOLOGY**

Myocarditis is an inflammatory condition that causes myocardial damage, usually because of infectious, immunologic, or toxin-mediated conditions (Box 60.2). Myocarditis can be manifested as mild constitutional symptoms, moderate cardiopulmonary symptoms, or fulminant cardiopulmonary decompensation leading to death. In the majority of adult cases, the myocardial damage is believed to be caused by autoimmune processes that are often triggered by viral or other infections, whereas in neonates and infants, injury to myocytes is believed to occur more often because of direct injury by the pathogen itself.

Approximately 10% of postmortem examinations demonstrate some degree of histologic evidence of myocarditis. However, most of the patients were not clinically symptomatic.

before death. Conversely, in patients in whom myocarditis is diagnosed clinically, only one third have histologic findings consistent with the disease. Even in cases that progress to dilated cardiomyopathy, only 40% of patients have microscopic evidence of myocarditis. Consequently, the actual incidence of myocarditis is unknown.

**PRESENTING SIGNS AND SYMPTOMS**

**CLASSIC**

The clinical manifestations of myocarditis usually begin days to weeks after the acute infection, especially when viruses are implicated as the cause. However, only 50% of patients report a recent upper respiratory or gastrointestinal viral type of infection. The initial symptoms are nonspecific and constitutional in nature: low fever, fatigue, malaise, myalgia, and arthralgia. These mild symptoms are often the reason for initial misdiagnosis or delays in proper diagnosis of this condition. Cardiopulmonary symptoms, especially mild dyspnea and chest pain, are common as well. The chest pain can be pleuritic, sharp, and positional, much like pericarditis, or substernal and squeezing, much like typical ischemic pain. Patients with congestive heart failure may report more significant dyspnea, as well as cough, orthopnea, paroxysmal nocturnal dyspnea, and edema. Less commonly, patients may initially be seen after a syncopal episode, usually the result of a bradydysrhythmia.

The physical findings are often notable for low-grade fever, tachypnea, and tachycardia. Classically, the patient has “tachycardia out of proportion to the fever”—extreme tachycardia without obvious hypovolemia or high fever (Fig. 60.5). Patients may also experience bradycardia if a high-grade atrioventricular block develops (Fig. 60.6). Evidence of congestive heart failure is frequently present as well: jugular venous distention, bibasilar rales on lung examination, a third heart sound (S₃) on cardiac examination, and peripheral edema. Patients with advanced or fulminant myocarditis may arrive at the ED in full cardiogenic shock.

**TYPICAL VARIATIONS**

Pediatric patients tend to have early, nonspecific symptoms, including fever, viral upper respiratory symptoms, and poor feeding. In more severe cases, the infant or neonate may exhibit severe tachycardia, tachypnea, sweating while feeding, respiratory distress, and cyanosis or other signs of poor perfusion. Tachydysrhythmias and bradydysrhythmias, especially those involving a high-grade atrioventricular block, are
common as well. Severe myocarditis in the very young is often also manifested as pulmonary edema, cardiogenic shock, and multiorgan hypoperfusion.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis of myocarditis is extremely broad because of the nonspecific nature of the initial findings. Patients who are initially seen with cardiopulmonary symptoms have a slightly more limited differential diagnosis, but initial consideration should as always be focused on the most deadly diseases that produce chest pain or dyspnea: acute coronary syndrome, aortic dissection, pulmonary embolism, acute pericarditis or pericardial tamponade, esophageal rupture, cardiogenic pulmonary edema, and pneumonia.

The initial diagnostic evaluation should be prompted by clinical suspicion. The finding of cardiopulmonary complaints, unexplained tachycardia, or evidence of congestive
heart failure on examination in young patients should prompt consideration of myocarditis. An ECG and chest radiograph are appropriate initial tests in these patients. Despite the absence of a specific or single diagnostic ECG abnormality, the majority of patients with myocarditis have at least some abnormality noted on the ECG. The most common abnormalities are sinus tachycardia (see Fig. 60.5) and nonspecific ST-segment or T-wave changes. Other abnormalities that may occur in patients with myocarditis are conduction abnormalities (new fascicular blocks, new bundle branch blocks, and atrioventricular blocks), atrial or ventricular tachydysrhythmias and bradydysrhythmias, overt ischemic changes (T-wave inversions, ST-segment changes), and Q-wave formation. The ischemic changes are often indistinguishable from those seen with true cardiac ischemia or myocardial infarction. If the pericardium is also involved (myopericarditis), PR-segment depression with concurrent ST-segment elevation may be found. If a pericardial effusion develops, low voltage may occur. The ECG findings are rarely completely normal.

Findings on plain chest radiographs are often frequently in mild or early cases of myocarditis. However, most patients with cardiopulmonary complaints have some radiographic signs of congestive heart failure: cardiomegaly, pulmonary vascular redistribution, interstitial edema, and frank pulmonary edema. Pleural effusions may be present as well.

Laboratory studies typically ordered in the ED include evaluation of markers of inflammation and cardiac biomarkers. Inflammatory markers, such as the white blood cell count, erythrocyte sedimentation rate, and C-reactive protein value, are expected to be elevated, but unfortunately, such elevations are nonspecific. Measurements of markers are sometimes used to monitor the course of the disease after the diagnosis is made. Cardiac biomarkers, including troponin and creatinine phosphokinase values, are also sometimes elevated. The initial elevations in cardiac biomarkers are frequently indistinguishable from those expected with acute myocardial infarction. Serial measurements of cardiac biomarkers can be helpful, however, because the levels do not tend to rise and fall as quickly with myocarditis as with myocardial infarction.

Echocardiography may also be helpful in the ED, especially when there is confusion in distinguishing between myocarditis and acute coronary syndrome. Echocardiography in patients with acute coronary syndrome (with active ischemia) usually demonstrates focal wall hypokinesis. Patients with myocarditis can also have focal hypokinesis, but they are more likely to have diffuse hypokinesis and multichamber dilation as well.23 In addition, the echocardiogram can demonstrate evidence of complications, such as pericardial effusion or intracardiac thrombus.

Endomyocardial biopsy is usually considered the “gold standard” for the diagnosis of myocarditis. Evidence of microscopic myocardial inflammation with various levels of necrosis is generally used to diagnose and categorize stages of myocarditis.24 However, biopsy is not feasible in the ED. Additionally, recent reports have questioned the sensitivity and specificity of the test.23,25

Other tests that can be ordered by the EP are viral cultures, blood cultures, and other immunologic studies. These tests are rarely helpful in the acute setting but may of use to inpatient physicians during the hospital course.

**TREATMENT**

Close attention should be paid to the ABCs of resuscitation because patients with fulminant myocarditis can decompensate rapidly. The mainstay of treatment of myocarditis is primarily supportive with a focus on hemodynamic support and management of complications. Congestive heart failure and hypoxia should be treated as usual, with high-flow oxygen, preload and afterload reduction, and diuretics. The patient’s fluid status must also be monitored closely because of the risk for congestive heart failure. Bradysyndrhythmias should be managed as usual. Patients with high-degree atrioventricular blocks often require pacemaker placement. Tachydysrhythmias should generally be managed as usual, although preference should be given to titratable medications because drugs with negative inotropic effects can precipitate unpredictable hemodynamic collapse in these patients with myocarditis, whose status is tenuous. Intramural thrombi noted on echocardiography should be treated with anticoagulation. The benefit of prophylactic anticoagulation is uncertain, especially given the risk that these patients have for hemopericardium. Additional myocardial workload reduction can be accomplished through fever reduction and correction of anemia.23

Patients in shock should be treated aggressively. Adequate perfusion should be achieved in hypotensive patients through the use of vasopressors (e.g., dopamine, norepinephrine) and positive inotropic agents (e.g., dobutamine). Ventricular assist devices, intraaortic balloon counterpulsation, and cardiopulmonary bypass have been used successfully in some patients during the wait for clinical improvement or cardiac transplantation.23

Antiviral therapy may be helpful during the patient’s hospital course if a viral cause of the myocarditis has been determined. Other therapies should be focused on the determined underlying condition (e.g., Lyme carditis, toxic-induced myocarditis). Immunosuppressive medications have been used successfully in some patients in the later stages of illness, but this experience appears to be anecdotal only.26 The use of corticosteroids lacks good evidence of benefit as well. High-dose intravenous gamma globulin has been used successfully in some pediatric patients, with improvement in ventricular function at 1 year.23

**FOLLOW-UP AND NEXT STEPS IN CARE**

Patients in whom myocarditis is suspected should be admitted to the hospital. Cardiac monitoring should be started to assess for the development of dysrhythmias, and close hemodynamic monitoring is indicated as well. Critical care, infectious disease, and cardiology consultants should be involved in the care plans for these patients. Because patients with severely decompensated cardiac conditions may require cardiac transplantation, appropriate surgical consultants should also be involved in the care of patients with severe myocarditis.

### REFERENCES

Of the four heart valves, three are tricuspid (aortic, pulmonic, and tricuspid) and one is bicuspid (mitral). Failure of normal function of these valves is due to lesions that make them incompetent and allow backward flow (regurgitation) or to lesions that decrease orifice size and cause restriction of flow (stenosis). In addition, combinations of these lesions may occur within the same valve, and multiple valves may be involved (commonly the aortic and mitral valves with rheumatic heart disease). Cardiac murmurs result from (1) increased blood flow across a normal or abnormal valve orifice, (2) turbulent flow across a narrow or irregular orifice into a dilated blood vessel or cardiac chamber, or (3) backward flow across an incompetent valve or other cardiac defect. However, most systolic murmurs are related to a physiologic increase in blood velocity and are not pathologic.

Physical examination establishes where the murmur occurs within the cardiac cycle and its location, duration, and intensity. Murmurs are classified as systolic, diastolic, and continuous. Systolic murmurs are further subclassified into holosystolic (pansystolic), midsystolic, early systolic, and late systolic. Clicks can be heard from the snapping shut of diseased valves. Diastolic and continuous murmurs are nearly always pathologic and require investigation, even in the absence of symptoms. Although many systolic murmurs merit investigation, especially those associated with symptoms, the majority of systolic murmurs do not signify valvular disease.2 A summary of the typical findings in the major valvular abnormalities is presented in Table 61.1.

A heart affected by valvular pathology has the ability to compensate over time, and symptoms are commonly absent for decades. Emergency physicians need to be able to identify when certain valvular lesions have progressed to the point that they are clinically important and responsible for the patient’s symptom complex. Shortness of breath, arrhythmias, and heart failure are common reasons why patients with VHD seek treatment at an ED. Other clinical scenarios include valve infection, myocardial infarction with papillary muscle dysfunction, and failure of a prosthetic device, which can cause rapid heart failure and shock. It should be kept in mind that valvular pathology is in the differential diagnosis of patients with congestive heart failure, shock, and angina. The clinician should perform a careful cardiac examination with attention to
to pulses, quality, and murmur types and locations. Does the patient with an aortic stenosis murmur have symptoms of angina pectoris, syncope, or heart failure? Are signs of embolic phenomena present in a patient with fever and a prosthetic heart valve? It is important to identify patients with severe aortic stenosis before using certain medications with preload effects because these drugs can cause significant hypotension.

Patients with midsystolic murmurs, grade 2 or less, and no associated findings or symptoms do not need any further work-up other than a history and physical examination. Aortic sclerosis is the most common defect found in these patients and requires no other intervention. However, patients with holosystolic murmurs, grade 3 murmurs, and diastolic or continuous murmurs should undergo further work-up with echocardiography. Some of these patients may eventually need cardiac catheterization if valve repair is planned. In patients with cardiopulmonary symptoms, detection of any new murmur warrants further investigation. The lack of a murmur in a patient with prosthetic heart valves may be pathologic and also requires further evaluation.

Clues about the significance of the VHD can be gleaned from chest radiography and electrocardiography (ECG). One may note valvular calcifications, asymmetric chambers sizes, and prosthetic valves. ECG may reveal signs of left atrial enlargement with tall or biphasic P waves, as well as left ventricular hypertrophy (LVH) or atrial fibrillation (AF).

A new diastolic murmur in a patient with chest or back pain should raise suspicion for aortic dissection and requires urgent testing and consultation, as well as control of the heart rate and blood pressure.

Patients with valvular heart disease may become hemodynamically unstable with rapid atrial fibrillation and require cardioversion.

Infectious endocarditis should be considered in all patients with a prosthetic valve and fever. Blood cultures and empiric antibiotics are indicated.

Beside echocardiography should be performed in patients with shortness of breath who have recently undergone prosthetic valve replacement to rule out pericardial tamponade.

**RED FLAGS**

A careful murmur examination should be performed in patients with chest pain. Individuals with severe aortic stenosis are dependent on preload to maintain systolic blood pressure, and treatment with nitrates can cause severe hypotension.

Patients in cardiogenic shock from acute mitral regurgitation, aortic regurgitation, or prosthetic valve dysfunction may not have an appreciable murmur and require emergency echocardiography. These conditions are treated surgically and will require cardiac surgery consultation.

Emergency physicians need to recognize that the absence of a murmur or mechanical heart sound is pathologic in a patient with mechanical heart valve prosthesis.

Be vigilant in patients with a bicuspid valve and chest pain because of an increased risk for aortic dissection in these individuals.

**SPECIFIC VALVE LESIONS**

**AORTIC STENOSIS**

Aortic stenosis (AS) is the third most common form of cardiovascular disease in the Western world after hypertension and coronary artery disease. The most common causes of AS are calcification of a normal tricuspid valve and a congenital bicuspid aortic valve. Calcific degeneration of the aortic valve results from an inflammatory process similar to atherosclerotic vascular disease; it begins with intimal injury, such as
calcification from the base of the cusps to the leaflets, which impairs motion, and progresses through fusion of valve leaflets and stenosis of the aortic valve orifice. When rheumatic heart disease is the culprit, the aortic valve commonly exhibits both stenosis and regurgitation and is usually associated with concomitant mitral valve disease.

The degree of aortic valve disease is based on several factors (Table 61.2). Such assessment may be inaccurate and underestimate valve area and jet velocity in patients with impaired cardiac output. Progression of AS is usually quite slow, with symptoms taking decades to become manifested in most cases. An average 0.1-cm² decrease in valve area occurs per year. The left ventricle is faced with systolic pressure overload and compensates through hypertrophy of the left ventricular (LV) wall. Normal chamber volume is maintained, but with increased wall thickness. The hypertrophic wall may lead to decreased coronary blood flow, even in the absence of stenosis and angina. Diastolic dysfunction and heart failure symptoms may also be present. These patients are dependent on forceful atrial contraction to maintain elevated LV end-diastolic pressure (LVEDP) to overcome the obstruction to outflow. Therefore, individuals who have AF and AS may suffer hemodynamic consequences from loss of the atrial kick.

Auscultation reveals a systolic murmur associated with diminished and delayed carotid pulses (parvus et tardus), a sustained LV impulse on palpation, and a decreased or absent aortic component of the second heart sound (S₂). Parvus et tardus may not be readily apparent in the elderly because of decreased compliance of the aging arterial vessels. Chest radiography may show normal heart size (remember concentric LVH) with rounding of the LV border. ECG can show LVH with a repolarization abnormality, which is seen in 85% of patients with severe AS. Echocardiography is indicated every year for patients with severe AS to assess the severity of the AS, wall thickness, and LV function. Exercise stress testing may lead to complications in patients with symptomatic AS and should not be performed.

Asymptomatic patients with AS have the same life expectancy outcome as age-matched controls. Once symptoms appear, the average survival is 2 to 3 years, with a risk for sudden death (<1% per year). Angina develops in 35% of patients, syncope in 15%, and congestive heart failure or dyspnea in 50%.

No medical treatment has been shown to decrease progression of disease in the leaflets, although statins are currently being studied. Significant care should be taken when treating these patients with preload-reducing agents (nitrates) because the sudden decrease in preload can cause severe hypotension, which in turn can lead to decreased coronary flow and worsen ischemia and shock. Cardiac catheterization is indicated in patients who have a discrepancy between the clinical complex and the results of echocardiography. Patients in whom cardiac surgery is planned need to undergo cardiac catheterization to assess the need for a concomitant coronary artery bypass grafting (CABG) procedure. The average mortality in patients who undergo aortic valve replacement (AVR) is 3% to 4% and, when associated with a CABG procedure, 5.5% to 6.8%. Percutaneous valvuloplasty is the use of a balloon to fracture calcium deposits in the leaflets. It results in immediate improvement in valve gradients; however, restenosis occurs in 6 to 12 months, and it is therefore not recommended for definitive treatment. This procedure has been used as a temporizing measure in patients who are not initially AVR candidates. Procedures are now available that allow percutaneous AVR in such patients.

### AORTIC REGRUTATION

Multiple conditions can cause aortic regurgitation (AR); the most important for the emergency department (ED) physician are aortic dissection, trauma, and endocarditis. Patients with congenital bicuspid valves are also at risk for both AI and dissection. Rheumatic heart disease is still the most common cause of AR worldwide. Cardiac examination in patients with AR reveals a murmur during diastole, more low pitched and associated with a widened pulse pressure and displaced LV impulse. Eponyms associated with AR include Corrigan pulse (rapid rising pulse that falls rapidly), Quincke pulse (capillary pulsations at the base of the nail when pressure is applied at the tip), and the Duroziez sign (to-and-fro murmur over the femoral arteries).

Patients with acute AI have a sudden large regurgitant blood volume. Because the heart has not had time to compensate, large rises in LVEDP and left atrial pressure and a decrease in stroke volume occur. Patients are seen in shock, with hypotension and pulmonary edema. If the LVEDP and aortic pressure gradients are close enough, decreased coronary blood flow and myocardial ischemia can develop. This low gradient may make it impossible to hear a murmur. Emergency bedside echocardiography with color flow Doppler imaging is necessary to establish the diagnosis.

Medical management of acute AI should be directed toward reducing afterload and increasing contractility. Combinations of nitroprusside and dobutamine may augment forward flow and reduce regurgitant volume and LVEDP. Intraaortic balloon pump treatment is contraindicated because it increases regurgitant volume as it inflates during diastole. Ideally, patients with acute AR have a lesion that is surgically amenable and medical management is only a bridge to definitive therapy.

In patients with chronic AI the left ventricle has had time to compensate to the increased volume by increasing both LV end-diastolic volume and LV wall compliance. This allows accommodation of the increased regurgitant volume without significantly increasing chamber pressure. Stroke volume is increased to make up for the backward flow volume.

Echocardiography is essential in the diagnostic management of patients over time. Patients who have AI, normal LV function, and no symptoms do not need any medical treatment. Valve replacement is recommended in patients with severe AR or LV dysfunction, regardless of whether they are

SECTION VI - CARDIAC DISORDERS
symptomatic. Medical therapy with vasodilating drugs (nifedipine, hydralazine, angiotensin-converting enzyme inhibitors) is reserved for patients with severe AR who are not surgical candidates or as short-term treatment before valve replacement. Beta-blockers will theoretically increase time during diastole and worsen the amount of regurgitant volume. The rate of progression from an asymptomatic patient with normal LV function to an asymptomatic patient with LV dysfunction is 3.5% per year. Once LV dysfunction is detected on ultrasound, most patients will become symptomatic in 2 to 3 years.

**MITRAL STENOSIS**

The normal mitral valve has an area of 4 to 5 cm², and symptoms usually begin when the valve area becomes less than 2.5 cm². Mitral stenosis (MS) nearly always results from previous rheumatic fever. In fact, a history of rheumatic fever can be elicited in up to 60% of patients with MS. A period of 20 to 40 years may transpire between the occurrence of rheumatic fever and the onset of symptoms, and another 10 years may elapse before these symptoms become disabling. The ratio of women to men with MS is 2:1. MS can also result from severe degenerative calcification, especially in the elderly. Dyspnea is the cardinal symptom of significant MS. Shortness of breath may not develop in patients with milder MS until AF with rapid ventricular response or pregnancy occurs or it is precipitated by exercise or infection.

Because the main problem in MS is obstruction to blood flow, no medical therapy is available that will relieve this obstruction. The principal treatment is surgical repair or valve replacement. Beta-blockers will cause bradycardia and increase diastolic filling time and may benefit patients in whom symptoms develop secondary to tachycardia. Anticoagulation is indicated in patients with MS and AF because systemic embolization occurs in 10% to 20% of patients with MS.

Percutaneous mitral balloon valvotomy in the hands of skilled operators can be the procedure of choice in patients with moderate to severe MS who are symptomatic (significant MR and left atrial thrombus are contraindications to this procedure). Open surgical commissurotomy and mitral valve replacement are other alternatives for mitral valve treatment.

**MITRAL REGURGITATION**

Causes of mitral regurgitation (MR) can be split into organic and functional categories. Organic causes include mitral valve prolapse (MVP), rheumatic fever, endocarditis, and certain medications (most recently the use of diet supplements). The most common functional cause of MR is secondary LV dilatation leading to a dilated annulus. Other functional causes include ruptured chordae tendineae, ruptured papillary muscle, and infective endocarditis. Patients with MR may exhibit a holosystolic murmur in association with a first heart sound (S₁) that is soft or absent and, frequently, a normal second heart sound (S₂).

Patients with acute MR have acute volume overload on the left atrium and left ventricle and, given lack of time for compensation, both decreased cardiac output and increased pulmonary congestion. The role of medical therapy is limited to stabilizing the patient’s hemodynamics before surgery. Diminishing MR, increasing forward flow, and improving pulmonary congestion can all be accomplished by afterload reduction with nitroprusside (if the patient can tolerate it) or an inotropic medication (dobutamine). An in-traaortic balloon pump can also be used as a temporizing measure before definitive treatment. Therapy for acute papillary muscle rupture is emergency valve repair or replacement.

Clinically, however, most patients will have chronic MR. The heart will compensate by increasing LV size (the usual mechanism for chronic volume overload). This increased size allows a higher volume at lower pressure. The duration of this asymptomatic chronic phase is about 6 to 10 years. Patients with ischemic cardiomyopathy can be treated with beta-blockers and angiotensin-converting enzyme inhibitors. AF rate control is also important. In patients with severe MR who are symptomatic, as well as in asymptomatic patients with severe MR and an ejection fraction of 30% to 60%, surgical therapy is indicated and includes mitral valve repair or replacement.

**MITRAL VALVE PROLAPSE**

MVP is defined as billowing of the leaflets into the left atrium with or without associated MR. Current estimates of MVP based on newer diagnostic criteria suggest that less than 2.5% of the population is affected. Familial causes may represent a manifestation of connective tissue disease. Patients with MVP may experience chest pain, anxiety, palpitations, and dyspnea. Physical examination reveals a midsystolic click, frequently in association with a late systolic murmur. Patients suspected of having MVP should arrange follow-up with a cardiologist or primary care physician and will probably undergo echocardiography. Patients with MVP who have had a transient ischemic attack or cerebrovascular attack should be treated with daily acetylsalicylic acid.

**ENDOCARDITIS AND RHEUMATIC FEVER PROPHYLAXIS**

Recently, guidelines for the prophylaxis of infective endocarditis have undergone changes based on working group review. No randomized controlled trial examining the efficacy of prophylaxis before procedures has ever been conducted. In fact, endocarditis is more likely to be related to random bacteremia with daily activities than to specific dental, gastrointestinal, or genitourinary procedures. Therefore, prophylaxis would prevent only a very small number of cases. Because antibiotics have side effects, in many scenarios the risk exceeds any possible prophylactic benefit. High-risk events include dental procedures that involve the gingiva. Prophylaxis would be recommended in (1) patients with prosthetic valves or prosthetic material, (2) patients with a history of endocarditis, (3) patients with valve disease and a transplanted organ, and (4) high-risk patients with congenital heart disease. Antibiotic prophylaxis is not recommended for gastrointestinal or genitourinary procedures or for respiratory procedures.

Patients who have previously had rheumatic fever are at higher risk for the development of another episode of rheumatic fever. Because antibiotics have been shown to prevent recurrent attacks, prophylaxis with penicillin or an antibiotic of the macrolide class is recommended.

**PROSTHETIC VALVE DISORDERS**

Valve repair and replacement surgery are common procedures that have been significantly refined over the past 40 years, and approximately 100,000 prosthetic valves are implanted in
patients in the United States and 300,000 worldwide. Prosthetic heart valves are divided into two broad classes, mechanical and biologic. Mechanical valves have evolved considerably since their introduction in 1965 with the Starr-Edwards ball valve. Shortly thereafter, in 1969, disk valves were introduced with the Björk-Shiley valve. Problems involving strut malfunction led to discontinuation of this valve in the United States in 1986. Bileaflet valves, including the St. Jude valve, which was introduced in 1977, are the most commonly implanted mechanical valves today.

Biologic valves are used in patients in whom long-term systemic anticoagulation is less desirable, and their use must be balanced against the need for reoperation because these valves will degenerate over the years. The most common biologic valve in the United States is the Carpentier-Edwards valve. Valves in the mitral position are at higher risk for thrombus formation than are valves in the aortic position, and some clinicians will treat bioprosthetic valves in the mitral position with warfarin.

A lateral chest radiograph can help in identifying a prosthetic valve. An imaginary line is drawn from the cardiac apex to the carina. Valves above this line are aortic and pulmonic, whereas valves below this line are mitral and tricuspid (Fig. 61.1).

Early complications after valve replacement include pericardial effusion with tamponade (pericardial inflammation and bleeding, which is exacerbated by anticoagulation), perioperative myocardial infarction, Dressler syndrome, AF, and early endocardial infection. Late prosthetic valve complications include AF, thromboembolic phenomena, endocarditis, valve malfunction as a result of thrombus or tissue ingrowth (pannus formation), and mechanical hemolytic anemia. Valve complications should be considered in any patient with a prosthetic valve who has symptoms of dyspnea, syncope, angina, or fever or has neurologic signs or symptoms. Absence of a murmur does not rule out prosthetic valve dysfunction. Cardiologic consultation and admission for further evaluation are warranted. In patients with mechanical heart valves and reversal of the international normalized ratio (INR) who have previously had thromboembolism, cessation of warfarin therapy is associated with a 10% to 20% annual risk for recurrent thromboembolism. Therefore, the risk is relatively small for reversal if brief (days), and these risk-benefit decisions must be individualized: Because its onset of action of vitamin k is delayed, its use should be avoided because it will only lead to a prolonged time for achieving a therapeutic INR once warfarin is reinstituted.

**TREATMENT**

In all patients with VHD, the goals of the emergency physician are to (1) determine whether valvular abnormality is the cause of the signs and symptoms, (2) optimize the hemodynamic status of patients who have suffered acute decompensation, (3) remember that certain subgroups of patients may need prophylaxis for endocarditis, and (4) make the appropriate consultations with cardiology and surgery.

Patients with new heart murmurs should undergo focused physical examination, ECG, and chest radiography. The outpatient area is usually the venue for asymptomatic patients. Innocent murmurs will not need any further evaluation, whereas other murmurs will require outpatient echocardiography; communication with the patient’s primary care physician or cardiologist (or both) is essential.

It is critical to consider VHD as a cause of the symptoms in all patients with shock, dyspnea, chest pain, syncope, or other symptoms that are consistent with worsening heart failure or arrhythmia. Echocardiography is recommended for all symptomatic patients in whom the findings on evaluation are consistent with valvular abnormality, as are hospital admission and cardiology consultation. It may be difficult to establish a valvular cause of cardiogenic shock based on physical examination only, and these patients will require emergency echocardiography.

Management of patients with acute valvular decompensation requiring stabilization and hemodynamic support is similar to that for any critically ill patient and begins with airway management. Assessment of circulation includes examination of the pulse, blood pressure, and systemic oxygen delivery. Skin color, temperature, capillary refill time, and measurement of serum lactate and B-type natriuretic peptide should be performed. Maneuvers should then be undertaken to improve cardiac output to meet systemic oxygen demand. Treating shock in patients with acute valvular disorders requires a thorough understanding that maximizing cardiac output and systemic oxygen delivery does not necessarily mean increasing blood pressure. Similarly, patients with pulmonary congestion may not all benefit from a significant reduction in circulating volume or preload. In general, patients who are hypotensive should benefit from volume infusion unless they exhibit overt signs or symptoms of pulmonary edema. However, in patients with MR, greater preload or volume may result in an increase in mitral orifice size and thus in regurgitant volume. In patients in whom an acute coronary...
Cardiac valvular disorders can present with a wide range of symptoms and require appropriate management. Emergency diagnostic cardiac catheterization may be appropriate if a pericardial effusion is suspected, as it can hasten the work-up for aortic arch dissection.

**DISPOSITION**

Medical and surgical management of patients with VHD is based on symptomatology and echocardiographic measurements. Therefore, patients seen in the ED with symptoms and findings on physical examination, ECG, and chest radiography consistent with valvular dysfunction need an expedited work-up and should be admitted to the hospital for echocardiography and cardiology evaluation. Patients in cardiogenic shock will need intensive care unit management, and if a valvular cause is strongly being considered, such management should occur at an institution with the capability of cardiac surgery because emergency valve surgery may be needed. Prosthetic valve endocarditis should be considered in all patients with artificial valves who exhibit fever, congestive heart failure, or thromboembolic phenomena. Antibiotics need to be instituted empirically after adequate blood is obtained for culture.

**DOCUMENTATION**

Intensity (grade 1-6 out of 6), timing during the cardiac cycle, location, and radiation are the principal ways to characterize a cardiac murmur.

Comment on heart size and chamber enlargement on the chest radiograph and whether left ventricular hypertrophy is present on the electrocardiogram.

Document the rationale if transfer is required for urgent cardiology or cardiothoracic surgery consultation.

Document risk-benefit discussions with patients and consultants when reversing anticoagulation in patients with mechanical prosthetic valves.

REFERENCES

Endocarditis is an inflammation of the endothelial lining of the heart. It is usually focal and commonly occurs at points of endocardial injury. The mitral and aortic valves are the most common sites of involvement.

- Most sites of endocardial injury become seeded with bacteria during episodes of transient bacteremia and thus develop into infective endocarditis.
- The initial symptoms are often vague—low-grade fever, malaise, and weakness.
- Manifestations can vary from direct structural cardiac injury to conduction system disturbances, embolic phenomena, and cardiogenic or septic shock.
- Suspicion of infective endocarditis should be raised by the presence of well-known risk factors, such as acquired or congenital valvular or structural heart disease, a prosthetic valve, implanted medical devices, injection drug use, and a previous history of endocarditis.
- Laboratory testing is often not useful for the emergency physician, but at least three sets of blood cultures performed over time are critical for the diagnosis of infective endocarditis, as well as for guiding subsequent therapy.
- The most useful initial diagnostic test is echocardiography.
- In an acutely ill patient, prompt resuscitation, antibiotics, and surgical consultation are imperative.
- In a stable patient with subacute disease, time until initiation of antibiotic therapy is less critical than performance of serial blood cultures.
- Nearly all patients with infective endocarditis require hospital admission. Only the most stable patients with no complications in whom the diagnosis of infective endocarditis is being entertained but not confirmed may be discharged with very close follow-up care.
- Despite medical advances, the overall mortality for both native valve and prosthetic valve infective endocarditis still ranges from 20% to 25%.
- Prevention of disease is most important. In 2007 the American Heart Association issued revised guidelines for antibiotic prophylaxis in patients at risk for endocarditis.

**KEY POINTS**

**EPIDEMIOLOGY**

Endocarditis is an inflammation of the endothelium, or inner lining, of the heart or heart valves (or both). The disrupted endothelium is very susceptible to seeding with infectious agents such as bacteria, viruses, and fungi, a condition known as infective endocarditis (IE). Recognized by medical science for more than 400 years, IE remains an illness that is difficult to diagnose and treat and still results in significant morbidity and mortality.

Over the last 30 years, published reports regarding the overall incidence of IE have conflictingly cited both a stable incidence and a rising incidence.\(^1\)\(^2\) Mortality ranges from 5% to 50% or higher. The reason for such variation in the statistics is that IE is a diverse and evolving disease entity—one that is strongly influenced by the characteristics of both the human and microbial populations being studied (Table 62.1).

In the developed world, IE has undergone a remarkable transformation over the last century. In the developing world, however, it has remained rather unchanged. Much of this difference is a result of the influence of advances in health care (e.g., antibiotics, disease prevention, medical devices, the resulting longevity of populations), as well as the complications that arise from these advances (e.g., nosocomial infections and resistant organisms).\(^4\)\(^5\)

Unfortunately, the tremendous advances made in health care have not translated into the gains that we have seen in other infectious diseases in the last 50 to 80 years. Untreated, IE has a mortality of nearly 100%. When treated, however, IE is still associated with a mortality rate of 20% to 25%.\(^5\) The overall incidence of IE in the developed world has remained unchanged.\(^1\) Why has the advent of antibiotics, advanced critical care and surgical techniques, and medical devices such as prosthetic valves not made a difference in this statistic? There are several reasons.

First, with a low prevalence, no pathognomonic signs or symptoms, and no single diagnostic front-line test, IE remains difficult to diagnose. Therefore, many cases are missed or diagnosed only when the disease is advanced. Second, despite the effective control of rheumatic heart disease in the developed world, new risk factors have arisen to fill the void. Degenerative heart disease in the growing elderly population has replaced rheumatic fever as the major cause of valvular disease. The same intravascular medical devices that have improved survival for patients (e.g., valvular prosthetics, cardiac pacemakers, long-term indwelling vascular catheters)

predispose them to the development of IE (regardless of whether they have had IE in the past). Third, the number of patients at risk for IE has increased—the elderly, patients receiving critical care, and immunocompromised patients (because of acquired immunodeficiency syndrome, diabetes mellitus, end-stage renal disease, chemotherapy, and other reasons). Risky social behavior, such as body piercing and injection drug use, is practiced more today than in the early 20th century. Finally and most concerning of all, burgeoning antibiotic resistance is making treatment of IE more challenging and sometimes unachievable.6

Because prevention and early diagnosis are the keys to reducing the morbidity and mortality associated with IE, emergency physicians (EPs) must play an important role in this process. Vigilance is key. EPs must consider the diagnosis when patients with risk factors for IE are seen in the emergency department (ED) with subtle symptoms. EPs must provide education to patients who are at high risk for IE and must provide prophylaxis for IE when warranted.

PATHOPHYSIOLOGY

The term endocarditis literally means inflammation of the inner lining or endothelium of the heart or lining of heart valves (or both). Local or systemic stressors, such as trauma, blood-borne contaminants (e.g., talc from injection drug use), inflammation, and abnormal blood turbulence, induce injury to the endothelium. Clinically relevant endocarditis results from the formation of a fibrin and platelet cap on the area of altered surface endothelium. Most commonly, a sterile cap forms at a site of endothelial injury. IE occurs when microbes adhere to these sites of sterile endothelial injury during transient periods of bacteremia, fungemia, or viremia. Colonization occurs, followed by microbial multiplication and growth of each cap into a vegetation (Figs. 62.1 and 62.2). Because of their direct contact with the bloodstream, these infections cause a continuous, albeit low-level presence of microbes in the blood. The clinical manifestations of endocarditis are quite varied as a result of immunologic, infectious, and embolic factors.
processes. It is this variation in manifestations that often makes endocarditis difficult to identify.

**MICROBIOLOGY OF INFECTIVE ENDOCARDITIS**

Although the microbiology of IE can predict the course of a patient’s illness and guide therapy, the actual infecting organism is rarely known to the EP. The EP needs to know the microbes that cause IE (Box 62.1) and the local resistance patterns to make sound choices regarding empiric antibiotic treatment regimens. This section discusses the organisms most commonly associated with IE. Certain patient characteristics and clinical scenarios are associated with particular microorganisms (Table 62.2). These scenarios may guide the EP’s choice of empiric antibiotics; specific regimens are discussed later in this chapter (see Table 62.4).

*Haemophilus species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

**BACTERIA**

**Viridans Group Streptococci**

*Streptococcus viridans*, formerly a species name, is actually a group of gram-positive cocci. This group has been the most common cause of IE, although more recent case series have shown that *Staphylococcus aureus* may now be more common. These streptococci usually seed previously damaged cardiac tissue. The clinical findings are usually more insidious, however, with patients experiencing malaise, weakness, and low-grade fever.

**Staphylococcus aureus**

Studies have now identified *S. aureus* rather than the viridans group of streptococci as the most common cause of IE. *S. aureus* can infect normal valvular endothelium—that is, endothelium without antecedent damage or disease—and usually causes aggressive valve destruction. It is associated with injection drug use, as well as with prosthetic valve endocarditis that occurs more than 1 month after surgery.

Over the last decade, the story of *S. aureus* and *S. aureus* IE has become increasingly complicated with the emergence of methicillin-resistant *S. aureus* (MRSA), as well as the subsequent identification of community-associated (CA-MRSA) and hospital-associated (HA-MRSA) subtypes. CA-MRSA has a tendency to affect previously healthy individuals but has a drug sensitivity pattern more favorable than that of HA-MRSA. HA-MRSA tends to affect the infirm (hospitalized, nursing home, elderly, preterm, and immunocompromised patients) and has a limited sensitivity pattern. A review of cases of native valve IE caused by these organisms reveals a higher mortality rate with HA-MRSA (37%) than with methicillin-sensitive *S. aureus* and CA-MRSA (23% and 13%, respectively).

**Staphylococcus epidermidis**

*S. epidermidis* is an organism associated with prosthetic valve endocarditis, especially that occurring within 1 month of surgery. The course of IE attributable to this organism is usually aggressive.

**Streptococcus bovis**

Infective endocarditis caused by *S. bovis* occurs more commonly in the elderly and often originates from a gastrointestinal (GI) source. It is commonly associated with GI polyps, inflammatory bowel disease, and GI malignancy.

**Streptococcus pneumoniae**

*S. pneumoniae* is an aggressive organism that frequently causes an acute, fulminant illness. It can infect normal heart valves, most often the aortic valve, with a high risk for the development of perivalvular abscesses or pericarditis. Pneumococcal endocarditis can occur in association with pneumococcal pneumonia and meningitis in a grouping called the Austrian triad.

**Enterococci**

Enterococci are normal flora of the GI tract and, occasionally, the anterior urethra. IE caused by one of these organisms usually runs a subacute course, but cure is often difficult because of the bacteria’s intrinsic resistance to antibiotics. The
The relapse rate is high after standard therapy. Typically, this problem occurs in older men after genitourinary manipulation and in middle-aged women after obstetric procedures.

**Pseudomonas aeruginosa**
A rare cause of IE, *P. aeruginosa* is an aggressive gram-negative bacterium. IE caused by this organism usually complicates the course of critically ill patients and injection drug users.

**Culture-Negative Bacteria**
The culture-negative bacteria group infrequently causes IE. These bacteria are characterized as culture negative because they either grow slowly in routine media, require special media to grow, or cannot be cultured. If clinical suspicion exists, the clinician must ask that blood cultures be held for a prolonged incubation period (14 to 21 days), request special culture media, or use the serologic and polymerase chain reaction assays available for some of these
infective SB. Calderwood Mylonakis from endocarditis nonspecific viral syndrome may often be diagnosed. Without high clinical suspicion, a tis are poor. The clinician must combine these findings with immunodeficiency virus, malignancy, organ transplantation), and injection drug use.9 Fungal IE usually produces large vegetations and is an indication for surgical intervention.

**Fungi**
Fungi are rarely a cause of endocarditis, but fungal IE has that commonly colonize the human oropharynx.

**Presenting Signs and Symptoms**
IE can vary greatly in the severity of its manifestations. Depending on the extent of the injury, location of the injury, microorganism involved, and comorbid conditions in the patient, IE can be an insidious chronic or subacute disease or an aggressive, rapidly debilitating process. Recent prospective cohort data from an international multicenter study have revealed that the acute manifestation is becoming more common—perhaps because of the increasing prevalence of S. aureus IE.7

The diagnosis of IE is challenging in both its insidious and acute forms. When the findings are subtle, a more benign diagnosis, such as a nonspecific viral syndrome, may be blamed for the illness. When the manifestation is acute and critical, a diagnosis in accordance with the syndrome (e.g., congestive heart failure [CHF], sepsis, heart block, stroke) may be made—with failure to identify the underlying cause (endocarditis). In both scenarios there is continued morbidity and possibly mortality.

EPs must maintain high clinical suspicion in situations associated with IE. Patients at high risk for IE are listed in Box 62.2. In such patients, sepsis, embolization, or cardiac failure or shock should warrant an evaluation for endocarditis. By understanding the pathophysiology of this disease, the clinician can predict the signs and symptoms that might be seen with IE.

**Classic Triad**
The triad consisting of fever, heart murmur, and anemia has classically been ascribed to the diagnosis of IE. Unfortunately, the sensitivity and specificity of these findings for endocarditis are poor. The clinician must combine these findings with high-risk patient characteristics (see Box 62.2).

**Organ-Specific Clinical Findings**
Most commonly, patients with IE have symptoms of malaise and fatigue in the setting of a low-grade fever. Most of this probably reflects the immunologic response to constant bacteremia. Patients may complain of generalized weakness with anorexia and weight loss. Without high clinical suspicion, a nonspecific viral syndrome may often be diagnosed.

**Vascular Signs and Symptoms**
Septic embolization of the vasa vasorum (blood vessels that feed large blood vessels) can lead to the development of mycotic aneurysms in any of the body’s larger arteries. Patients can exhibit pain, lightheadedness, altered mental status, and even syncope from the vascular insufficiency or hemorrhage that may occur at any of the sites of involvement.

The signs and symptoms that may be seen with involvement of specific vascular sites are as follows:
- • Central nervous system (CNS) arteries—headache, focal neurologic deficits, confusion
- • Sinus of Valsalva—pleuritic chest pain, muffled heart tones
- • Hepatic artery—right upper quadrant pain, hematemesis
- • Splenic artery—abdominal pain, intraabdominal hemorrhage
- • Renal arteries—flank pain, hematuria
- • Intestinal arteries—abdominal pain, intraabdominal hemo-

**Cardiac Signs and Symptoms**
Cardiac symptoms of IE include chest pain, shortness of breath, lightheadedness, and even syncope. These symptoms can result from a variety of heart-specific processes.

Valvular damage can lead to valvular insufficiency (and murmur), which may progress to CHF and even frank cardiogenic shock, especially with left-sided valve involvement. With right-sided valve endocarditis, right heart failure with hepatosplenomegaly and peripheral edema might be evident.

Intracardiac abscess formation causes clinical compromise in a number of ways, depending on the cardiac structure involved. Erosion into the conduction system can lead to all manner of heart blocks, including complete heart block. Involvement of the valvular annulus can result in valvular incompetence and heart failure or may lead to erosion into the pericardial space and cardiac tamponade. Cardiac wall abscesses can give rise to septal or free wall rupture or to valvular compromise as a result of papillary muscle rupture.

Embolization of endocarditis vegetations to the coronary arteries can cause diffuse myocarditis via diffuse seeding of the myocardium. Myocardial infarction may occur through

---

**Box 62.2 Risk Factors for Infective Endocarditis**

- Acquired or congenital valvular and structural heart disease, including mitral valve prolapse, rheumatic heart disease, and hypertrophic cardiomyopathy
- Prosthetic valves, including bioprosthetic devices
- Implantable medical devices (cardiac pacemakers, long-term indwelling vascular catheters, implantable defibrillators)
- Injection drug use
- Poor dental hygiene
- Long-term hemodialysis
- Diabetes mellitus
- Previous history of endocarditis
- Immunocompromised states

direct intraluminal embolization and coronary artery occlusion or through embolic seeding of the coronary vasa vasorum and the formation of coronary mycotic aneurysms.

**Pulmonary Signs and Symptoms**
Pulmonary complaints need not be present in patients with IE. Common pulmonary symptoms are dyspnea and cough. Pulmonary complaints related to embolization may accompany right-sided IE—tricuspid or pulmonic valve endocarditis. Patients may have pneumonia secondary to pulmonary septic emboli. Ventilation-perfusion mismatching may develop as a result of pulmonary embolization. Left-sided endocarditis can lead to pulmonary congestion secondary to cardiac failure and acute pulmonary edema.

**Neurologic and Psychiatric Signs and Symptoms**
Endocarditis can be accompanied by myriad neurologic and psychiatric signs and symptoms. They can be a result of the systemic effects of hypotension and sepsis or a direct result of focal CNS embolization. Clinical findings may include confusion, complex changes in behavior, headache, seizure, stroke, or coma. The diagnosis of IE can be hard to make because of the large list of differential diagnoses for these symptoms.

**Ophthalmologic Signs and Symptoms**
The eye is not immune to endocarditis. Both embolic and immune phenomena can affect the optic nerves, ophthalmic vessels, conjunctivae, and retina. Initial complaints may include painless conjunctival hemorrhages, visual field cuts, and even monocular blindness. Emboli can cause infarction of the ophthalmic or retinal vessels and lead to loss of vision. Hemorrhages with pale cotton-wool centers known as Roth spots can be visualized on the retina (Fig. 62.3). EPs should be aware that these spots are not pathognomonic for IE but rather, if seen, should raise suspicion for this disease. Painless subconjunctival hemorrhages (Fig. 62.4), or petechiae involving the conjunctivae, can also be present and again are not specific.

**Hematopoietic Signs and Symptoms**
Weakness and fatigue can result from anemia, which can be associated with IE. Usually, the anemia is normocytic and mild. IE can also stimulate an immune response marked by leukocytosis and splenomegaly.

**Gastrointestinal Signs and Symptoms**
Nausea and vomiting are very nonspecific symptoms. In a patient with IE, these symptoms may accompany complications such as myocardial infarction, pericardial edema, and processes that increase intracranial pressure. Abdominal pain in patients with IE may be a manifestation of a nonspecific ileus, mesenteric ischemia from mesenteric emboli, or mycotic aneurysms of the splanchnic vasculature.

**Renal Signs and Symptoms**
Emboli to the kidneys can result in abscess formation, ischemia, and infarction. The resultant flank pain, pyuria, or hematuria (or any combination of the three) may easily be misdiagnosed as urolithiasis or pyelonephritis. Hematuria can also be a manifestation of glomerulonephritis from immune complex deposition related to IE.

**Dermatologic Signs and Symptoms**
The skin can give great clues to the presence of IE. Classic findings are Janeway lesions, Osler nodes, and splinter hemorrhages.

Janeway lesions are small, painless hemorrhages with a macular or slightly nodular character (Fig. 62.5). They are found on the thenar and hypothenar eminences of the palms and soles. The histologic findings are generally consistent with septic microemboli. Bacteria have been cultured from these lesions. Janeway lesions are usually present for days to

**Fig. 62.3 Roth spots.** Septic microemboli to the retinal arteries result in infarction. The ischemic cotton-wool centers are surrounded by hemorrhagic halos (arrows). These spots are not pathognomonic for endocarditis. (From Mandell GL, Bennett JE, Dolin R, editors. Principles and practice of infectious diseases. 6th ed. Philadelphia: Churchill Livingstone; 2005.)

**Fig. 62.4 Subconjunctival hemorrhages (arrow) in patient with viridans group streptococcal endocarditis.** (Courtesy Marc E. Grossman, MD, FACP.)
Splinter hemorrhages are linear petechiae visible on the nail beds of affected patients (Fig. 62.7). They do not blanch when pressure is applied to the nail and are seen better if a bright light is shone directly onto the distal tip of the digit.

Fig. 62.6 Osler nodes. (From Cohen J, Powderly WG, editors. Infectious diseases. 2nd ed. Philadelphia: Mosby; 2004.)

weeks before healing. They are most often associated with acute IE from *S. aureus*.

Osler nodes are small, tender, red to purple nodules. They are most often found on the pulp of the distal phalanges of the fingers and toes, the soles, and the thenar and hypothenar eminences of the palms (Fig. 62.6). Preceding the appearance of the nodes, patients often experience neuropathic pain. Although these nodes were initially believed to be purely immunologic in nature, reports have now isolated bacteria from them. It has been postulated that early microembolization with microabscess formation is followed by an immune-mediated hypersensitivity vasculitis. Osler nodes can appear at any point in the course of IE and can last a few hours to several days. They tend to be associated with subacute IE.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

**DIFFERENTIAL DIAGNOSIS**

Because of the many clinical manifestations of IE, the list of differential diagnoses is overwhelmingly large. Broad areas include infectious and febrile illnesses, as well as cardiovascular, neurologic, psychiatric, GI, renal, dermatologic, and immunologic disorders (Box 62.3). Most interestingly, IE can lead to manifestations that are diagnoses; the EP must think past that initial diagnosis and identify IE as the underlying cause. For example, a cerebrovascular accident or myocardial infarction may be secondary to the embolization or mycotic aneurysms of IE; this fact is important because therapy must also focus on treating the IE.

The most common illness in the differential diagnosis list for IE is febrile illness of any source. Viral syndromes, pneumonia, and urinary tract infections may cause fever, weakness, behavioral abnormalities, and even hemodynamic instability.

The most life-threatening entities are aortic catastrophes, myocardial infarction (with or without acute valve failure), complete heart block, massive pulmonary embolism, cerebrovascular accident, and sepsis.

As mentioned frequently in this chapter, high clinical suspicion guided by knowledge of risk factors (see Box 62.2) is the key to including IE in this long, complex list of differential diagnoses.
MEDICAL DECISION MAKING

Contributing to the complexity of IE is the fact that there is neither a single rapid test to diagnose the disorder nor any routine ancillary test that hints at the diagnosis. Some physical findings might clue the EP to this diagnosis, but they are nonspecific. For the EP, the most important tool for diagnosing IE is clinical suspicion. Elements of the history known to identify patients at high risk for endocarditis must trigger this suspicion and lead the EP to focus on physical findings typical of endocarditis. When suspicious for IE based on the history and physical findings, the EP must order serial blood cultures and an echocardiogram to confirm the diagnosis. A diagnostic algorithm is presented in Figure 62.8.

The most accepted diagnostic schema for IE is the modified Duke criteria (Box 62.4). Unfortunately for the EP, this approach relies heavily on blood culture and echocardiography, the results of which are rarely available to EPs at the outset of care. With recent efforts to bring ultrasonography skills to the ED bedside, echocardiography may become more readily available as an initial evaluation tool, but for now, the procedure requires cardiology consultation and is often not available during the first few hours of care.

According to the modified Duke criteria (see Box 62.4), an echocardiogram positive for IE along with presence of three minor criteria would allow the EP to actually make a “definite diagnosis” of IE in the ED. In all other cases, an echocardiogram positive for IE enables the diagnosis to be “possible IE” as the clinician awaits the results of blood cultures or serologic analysis. It must be emphasized, however, that normal
High suspicion for IE from history and physical findings

Perform ABCs of resuscitation and initiate stabilization procedures

Obtain CBC, serum chemistries, liver function tests, coagulation panel, ESR, C-reactive protein, type and hold/cross, troponin, blood culture, urinalysis, ECG, chest radiograph

Treat presenting disease processes (e.g., CHF, CVA, complete heart block) Simultaneously Attempt to diagnose and treat underlying IE

Assess acuity of IE presentation

Acute/unstable IE presentation

Native valve, low risk for IE by history, no focal infection evident

Prosthetic valve, high-risk history such as injection drug use, concomitant infectious illness (pneumonia, meningitis, abscess)

Order at least three sets of blood cultures from separate sites at least 30 minutes apart over 3-6 hours; may accelerate time course based on clinical need

1. Order echocardiogram*
2. Hold antibiotics pending blood culture results
3. Admit to monitored medicine service
4. Consider discharge if patient is very stable with close follow-up care

1. Order echocardiogram*
2. Begin empiric antibiotics (see Table 62-4)
3. Admit to monitored medicine service (discharge/not recommended)

Inpatient workup

Obtain echocardiogram*

Positive for vegetation

Start empiric antibiotics if not already started (see Table 62-4)

Echo positive for vegetation

Blood culture positive

Echocardiogram and blood cultures both negative

Alternative diagnosis established

Start or adjust antibiotics based on organism and sensitivities

1. Consider “culture negative” organisms
2. Consider alternative diagnosis
3. Continue to pursue IE as diagnosis

No vegetation noted

1. Await blood culture results
2. Look for alternative diagnosis
3. Repeat echocardiogram*

Fig. 62.8 Diagnostic algorithm for the emergency department management of patients in whom infective endocarditis (IE) is suspected.*Echocardiography can be performed via either the transthoracic (TTE) or transesophageal (TEE) technique. TEE is more invasive but is more sensitive for detecting vegetations and complications of IE, such as perivalvular abscesses; it is recommended for prosthetic valves; for situations in which optimal visualization by TTE will be difficult, such as emphysema and morbid obesity; for high suspicion of IE but normal TTE findings; and for high suspicion of a complication of IE, such as perivalvular abscess. Normal findings with either technique do not exclude IE if clinical suspicion is high. Echocardiograms can be repeated in an attempt to identify problems such as vegetations and abscesses that may not be noted initially. ABCs, Airway, breathing, and circulation; CBC, complete blood count; CHF, congestive heart failure; CVA, cerebrovascular accident; ECG, electrocardiogram; ESR, erythrocyte sedimentation rate; ICU, intensive care unit.
BOX 62.4 Modified Duke Diagnostic Criteria for Infective Endocarditis

**Stratification of Patients**
The modified Duke diagnostic criteria stratify patients with suspected infective endocarditis (IE) into one of three categories as follows: the major and minor criteria are listed below.

- **A diagnosis of “definite” endocarditis** is made in a patient with one of the following:
  - Histologic and/or microbiologic evidence of infection at surgery or autopsy
  - 2 major criteria
  - 1 major criterion and 3 minor criteria
  - 5 minor criteria

- **A diagnosis of “possible” endocarditis** is made in a patient with one of the following:
  - 1 major criterion and 1 minor criterion
  - 3 minor criteria

- **A diagnosis of endocarditis is “rejected”** in a patient with one of the following:
  - Negative findings at surgery or autopsy in a patient who received antibiotic therapy for ≤4 days
  - A firm alternative diagnosis
  - Resolution of illness with antibiotic therapy for ≤4 days
  - Failure to meet the criteria for “possible endocarditis

**Major Criteria**

- **Blood Culture Results Positive for Infective Endocarditis**
  1. Typical microorganisms causing IE from two separate blood cultures in the absence of a primary focus:
     - Viridans group streptococci
     - Streptococcus bovis
     - HACEK group of bacteria*
     - Community-acquired *Staphylococcus aureus* or *Enterococcus*
  2. Persistently positive blood culture results, defined as recovery of a microorganism consistent with IE from one of the following:
     - Blood culture specimens obtained more than 12 hours apart
     - All of 3 or a majority of 4 or more separate blood culture specimens, the first and last of which have been obtained at least 1 hour apart

**Minor Criteria**

- **Predisposition:** Predisposing heart condition or intravenous drug use
- **Fever:** Body temperature > 38.0°C (100.4°F)
- **Vascular phenomena:** Major arterial emboli, septic pulmonary infarcts, mycotic aneurysms, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
- **Immunologic phenomena:** Glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor
- **Microbiologic evidence:** Positive blood culture result but not meeting the major criteria as noted above (excluding a single positive culture result for coagulase-negative staphylococci and organisms that do not cause endocarditis) OR serologic evidence of active infection with an organism consistent with IE.

Echocardiographic findings would not eliminate the diagnosis of IE, especially in the setting of high clinical suspicion (high-risk patient, strongly suggestive findings). Evaluation should continue until the diagnosis of IE is “rejected” according to the modified Duke criteria. This often means establishment of an alternative diagnosis or the finding of sterile blood cultures after appropriate incubation procedures (proper media and incubation times) and resolution of the illness.

**DIAGNOSTIC TESTING**

Many diagnostic tests are available to help the EP evaluate and manage patients with possible IE. Many of these tests assist in identifying the complications of this disease process.

**LABORATORY TESTS**

Though not diagnostic when performed alone, some laboratory tests can be useful in diagnosing endocarditis and managing patients in the ED.

The complete blood cell count is less useful than one might think. Leukocytosis is present only in some cases. Normochromic normocytic anemia may be seen.

An elevated erythrocyte sedimentation rate or C-reactive protein value can be a good though nonspecific clue. Both findings are markers for an ongoing inflammatory process and are nearly always present in patients with IE.

Urineysis often shows proteinuria and sometimes hematuria. Proteinuria may occur as a result of the immunologic effects of endocarditis. Chronic infection or inflammation leads to the formation of immune complexes and their deposition in...
the glomeruli. Depending on the duration of this illness, the patient may have glomerulonephritis and renal insufficiency.

Renal function can be affected in patients with IE. A serum creatinine measurement is not useful for the diagnosis of IE, but it is for its management. Antibiotic dosing and the use of intravenous contrast–enhanced computed tomography (CT) are dependent on a patient’s renal function.

Less useful for the EP but part of the modified Duke criteria for IE are serologic tests. Rheumatoid factor may occasionally be found in patients with IE, particularly those with long-standing, indolent cases. Serologic assays can detect the presence of bacteria such as *Coxiella*, *Brucella*, *Bartonella*, *Legionella*, and *Chlamydia*. Polymerase chain reaction testing for specific DNA or RNA from blood, urine, or surgically excised tissue can be performed when the potential pathogen is slow growing or cannot be cultured by conventional methods.11

**MICROBIOLOGY**

Perhaps the most useful test for the diagnosis and management of IE is serial blood cultures. Unfortunately, the results of cultures are often not available to the EP. Three sets of blood culture specimens should ideally be collected before the initiation of antibiotics at intervals of least 30 minutes and over a period of 3 to 6 hours. There is little increased culture yield beyond three sets of blood cultures as long as they are obtained before the administration of antibiotics.

IE results in a constant, low-grade bacteremia. Therefore, it is not necessary to obtain blood culture specimens only during temperature spikes. Serial blood culture specimens obtained over a period of hours to days (in the absence of antibiotic therapy) should all yield positive results as long as at least 10 mL of blood per culture bottle is collected. In the interest of identifying endocarditis caused by more fastidious organisms, it is recommended that blood cultures be held for 14 to 21 days before being labeled negative.

The EP must remember that antecedent antibiotic treatment can also result in negative blood culture results, so the history should include questions about such treatment.11 In a stable patient with a history of antecedent antibiotic therapy, serial blood culture specimens should be collected over a longer time (even days) before initiation of antibiotic therapy for IE.

The caveat to the timing of serial blood sampling for culture is that withholding antibiotics should be the strategy in a stable patient who has no other indications for antibiotics. In an unstable or acutely ill patient, the three sets of blood culture specimens should be obtained over a period of 5 to 20 minutes and then antibiotics given as early as possible.

**ELECTROCARDIOGRAPHY**

Acquisition of an electrocardiogram (ECG) is often prompted by abnormalities in vital signs, initial symptoms, or clinical instability. If the EP suspects IE, an ECG must be performed. Abnormalities found on the ECG can be caused by endocarditis, but as with other findings for this diagnosis, these abnormalities are nonspecific. The pathologic findings that can be associated with endocarditis are acute myocardial infarction (secondary to coronary artery involvement), complete heart block, atrioventricular block, and bundle branch blocks. Infarction can occur as a result of direct embolization to the coronary arteries or coronary mycotic aneurysm formation. Conduction abnormalities can arise from direct extension of infection to the conduction system. Most commonly, the ECG in patients with endocarditis is normal or reveals a sinus tachycardia.

**ECHOCARDIOGRAPHY**

Echocardiography is the most important diagnostic tool available to the EP for the early identification of endocarditis and must be performed rapidly in all cases of suspected IE.6,12 It is one of the major criteria for the diagnosis of IE according to the modified Duke criteria (see Box 62.4 for echocardiographic findings that are diagnostic of IE10) (Fig. 62.9). In addition, echocardiography allows assessment of disease severity, complications, prognosis, and the need for surgical therapy. It is therefore a critical component in the initial assessment of a patient suspected of having IE.12,13

**Transthoracic Echocardiography**

Easily done at the bedside, transthoracic echocardiography (TTE) is recommended as the initial imaging modality. It can identify valvular damage and valvular vegetations, as well as assess cardiac function and pulmonary pressure. Its limitations lie in the assessment of patients with a prosthetic valve or intracardiac hardware.

**Transesophageal Echocardiography**

Although it requires more preparation and is more invasive than TTE, transesophageal echocardiography (TEE) has greater sensitivity and specificity (Table 62.3). It can visualize smaller vegetations, as well as myocardial involvement such as abscesses and prosthetic valve vegetations. TEE is recommended for patients with the following findings:

- The TTE result is negative, but clinical suspicion for IE is high.
- The TTE result is positive, but there is concern for the presence of a high-risk complication of IE, such as large or mobile vegetations, significant valvular insufficiency, or a suggestion of perivalvular extension.
- The TTE result is suboptimal because of, for example, morbid obesity, mechanical ventilation, emphysema, or chest wall deformity.
- Prosthetic valves are in place.
In patients with high clinical suspicion for IE, a normal echocardiographic result is not sufficient to discontinue diagnostic assessment or treatment. TTE or TEE should be repeated within 7 to 10 days. TTE or TEE can be used subsequently to assess the response to treatment or progression of the disease. Please see Figure 62.10 for the echocardiography algorithm.5,12

**RADIOGRAPHY**

Chest radiographs are obtained routinely in most patients with cardiopulmonary symptoms, fever, or both. No specific finding on the chest radiograph is pathognomonic for IE. Multiple bilateral pulmonary infiltrates might be a clue that septic emboli may be present (Fig. 62.11, A).

CT is an excellent tool for the evaluation of symptoms that may be associated with IE. The discovery of ischemic or infectious foci or abscesses, especially multiple lesions, should raise suspicion for a septic focus, such as IE. Contrast-enhanced CT is preferred for differentiating mass lesions with necrotic centers from abscesses.

Chest CT may better identify multiple septic emboli, effusions, or pulmonary abscesses (see Fig. 62.11, B). Brain CT for the evaluation of patients with neurologic or neuropsychiatric symptoms may demonstrate ischemic or infectious foci. Contrast-enhanced abdominopelvic CT might identify ischemia or infarction of the intestines, liver, spleen, or kidneys (Fig. 62.12). For identifying the presence of mycotic aneurysms or peripheral embolization, conventional angiography remains the “gold standard,” although screening may be undertaken with CT angiography or magnetic resonance angiography.

**LUMBAR PUNCTURE**

Lumbar puncture is not helpful in making the diagnosis of IE but is mandatory for diagnosing meningitis. Headache, neck stiffness, fever, alteration in mental status, or any combination of these symptoms should make one think of the diagnosis of meningitis. Independent of IE or a complication of IE, the diagnosis of meningitis—especially bacterial meningitis—must be made expeditiously. Lumbar puncture allows the EP to make the diagnosis of meningitis, initiate treatment, and ultimately, identify the causative organism.

**TREATMENT**

**RESUSCITATION**

Emergency treatment always begins with the cardinal ABCs of resuscitation—airway, breathing, and circulation. Patients with issues in any of these areas must be stabilized by the
usual methods. Supplemental oxygen or endotracheal intubation (or both) should be used as needed. Circulatory instability as a result of either cardiogenic or septic shock should be corrected with volume or pressor support, or both. Refractory cardiogenic shock may require the use of an intraaortic balloon counterpulsation device (contraindicated in patients with aortic insufficiency) or emergency heart surgery.

**EMPIRIC ANTIBIOTIC THERAPY**

Antibiotics are the keystone of treatment of IE, and selection of the proper regimen depends on the causative organism. Identification of the specific organism and its resistance pattern allows a properly tailored antibiotic regimen that minimizes the overuse of extended-spectrum agents. With this in mind, EPs should make every effort to obtain serial blood specimens for culture before starting antibiotic treatment. Three sets (aerobic and anaerobic) of blood culture specimens should be obtained. The sets should ideally be collected at least 30 minutes apart and over a period of 3 to 6 hours.

The urgency for empiric antibiotic therapy varies by patient subgroup. In stable patients with subacute manifestations and native valves who have signs and symptoms most consistent with a viral syndrome, antibiotic therapy can be withheld for hours and even days to allow proper culture results to be obtained. Patients with the same stable, subacute findings and viral syndrome–type symptoms but with a prosthetic valve or a history of injection drug use should be admitted to the hospital and receive appropriate empiric antibiotic therapy after the 3- to 6-hour collection of serial blood culture specimens. In a patient with a concomitant infectious process such as meningitis, pneumonia, or abscess and in whom the diagnosis of IE is being entertained, the serial blood culture specimens should still be collected but over a shorter time frame to allow sooner initiation of appropriate empiric antibiotic therapy to cover both the identified infection and the possible IE. Finally, in a patient with an acute, unstable manifestation of suspected IE, empiric antibiotics should not be withheld for collection of serial blood culture specimens. Three specimens can be collected over a 5- to 20-minute period to allow expeditious antibiotic treatment.

Unfortunately for the EP, the causative organism is rarely known because culture results are often not available yet. As with many infections, the EP must choose an empiric regimen. So how does the EP choose the empiric regimen? A group of organisms are known to cause IE (see Box 62.1). Certain of these organisms are more common, depending on the clinical scenario (see Table 62.2). Armed with this knowledge, the EP can tailor the empiric antibiotic regimen to the clinical scenario presented. Examples of such scenarios are native valve involvement, prosthetic valve involvement, injection drug use, history of allergy to antibiotics, prolonged hospitalization, admission to the intensive care unit, and a high prevalence of resistant organisms (Box 62.5). All these factors would influence the antibiotic regimen chosen.

Should the empiric regimen include antibiotics that cover all possible organisms and all resistance patterns? Actually, because many patients with IE have stable, subacute manifestations, the EP is not forced to achieve a perfect match of

Fig. 62.11  Septic emboli. A, A chest radiograph shows two nodular densities (arrows). In this case they are foci of infection from embolization of infected vegetations. B, This non–contrast-enhanced computed tomography scan of the chest demonstrates multiple small infiltrates (arrows) caused by septic embolization.
organism and antibiotic. Changes can be made in 2 to 3 days, when the organisms and resistance patterns become known. In contrast, for unstable, acute cases, EPs should maximize coverage to ensure that they account for all possibilities of organism and resistance. Morbidity and mortality could be influenced by failure to properly treat early.

Initial antibiotic therapy should always be parenteral and bactericidal. Because of growing antibiotic resistance, combination therapy with two or more agents should be used. Recommended empiric antibiotic regimens are listed in Table 62.4.

For complex cases, it is advisable to seek the expertise of an infectious disease specialist. In addition, patients with confirmed IE require prolonged antibiotic administration and will probably be discharged with a long-term central intravenous catheter such as a Groshong catheter or peripherally inserted central catheter.

**Box 62.5 Clinical Scenarios to Help Tailor an Empiric Antibiotic Regimen for a Patient with Suspected Infective Endocarditis**

Important factors in choosing an antibiotic are as follows:
- Acuteness of findings
- Native valve endocarditis
- Prosthetic valve endocarditis
- Endocarditis in an injection drug user
- Recent or current use of antibiotics
- Recent hospitalization
- Antibiotic allergies
- Renal function
- Relapse of previously treated endocarditis
- Regional prevalence of certain organisms and resistance patterns

**Table 62.4 Empiric Antibiotic Regimen for Presumed Infectious Endocarditis†‡§**

| Suspected native valve IE with a subacute manifestation¶ | Penicillin G, 200-400 U/kg (normal adult dose, 12-20 million U/day) IV divided q4h, or ampicillin, 200 mg/kg/day (normal adult dose, 12 g/day) IV divided q4h plus Nafcillin or oxacillin, 200 mg/kg/day (normal adult dose, 12 g/day) IV divided q4h plus Gentamicin, 1 mg/kg IV or IM q8h (adjust for peak serum concentration of 3-4 mcg/mL and trough of <1 mcg/mL)¶ |
| Suspected native valve IE with the following characteristics: Patient with penicillin allergy or Acute manifestation or History of injection drug use or From a region with a high incidence of IE caused by Staphylococcus aureus, especially oxacillin-resistant S. aureus | Vancomycin, 15 mg/kg IV q12h (adjust for 1-hr peak serum concentration of 30-45 mcg/mL and trough of 10-15 mcg/mL)¶ plus Gentamicin, 1 mg/kg IV or IM q8h (adjust for peak serum concentration of 3-4 mcg/mL and trough of <1 mcg/mL)¶ |
| Suspected prosthetic valve IE | Vancomycin, 15 mg/kg IV q12h (adjust for 1-hr peak serum concentration of 30-45 mcg/mL and trough of 10-15 mcg/mL)¶ plus Gentamicin, 1 mg/kg IV or IM q8h (adjust for peak serum concentration of 3-4 mcg/mL and trough of <1 mcg/mL)¶ Rifampin, 20 mg/kg/day (normal adult dose, 900 mg/day) PO divided q8h** |

*Empiric therapy must be designed on the basis of clinical and epidemiologic clues.
†The duration of therapy varies with the microorganism and its drug sensitivities, the presence of prosthetic devices, and the response to therapy.
‡The pediatric dose should not exceed the normal adult dose.
¶Penicillin G or ampicillin is added to this regimen because nafcillin/oxacillin and gentamicin may not be adequate coverage of enterococci.
§Aminoglycosides such as gentamicin should not be given as single daily doses.
¶Doses of vancomycin and gentamicin should be adjusted for reduced renal function, as well as measured serum concentration values.
**Rifampin increases the warfarin requirement for anticoagulation.

IE, Infectious endocarditis; IM, intramuscularly; IV, intravenously; PO, orally.
CARDIAC RACING
Any hemodynamically unstable patient with a complete heart block, irrespective of cause, warrants at least temporary cardiac pacing. In the setting of IE, in which a high-degree heart block is unlikely to be a temporary condition, a transvenous pacemaker is preferable to transthoracic pacing.

ANTICOAGULATION
Anticoagulation is not indicated for patients with endocarditis. It prevents neither the formation nor the embolization of vegetations. In the setting of native valve IE, anticoagulation should be avoided because it affords no benefit and might cause harm by converting CNS infarcts from bland to hemorrhagic.

Understanding the risks associated with anticoagulation in the setting of IE, what does the EP do with patients who would normally require anticoagulation? An excellent example would be a patient with IE and an anticoagulation-requiring prosthetic valve. The recommendation is that anticoagulation should be continued, barring the presence of acute hemorrhage, CNS infarction or hemorrhage, or a mycotic aneurysm. Any complaint that may result from these issues should be fully investigated to best inform decisions regarding anticoagulation. CT of the brain should be performed in any patient with possible CNS involvement. Any patient with unexplained abdominal or flank pain should undergo contrast-enhanced abdominal CT to evaluate for the presence of a mycotic aneurysm. Visual complaints warrant a complete funduscopic examination. If contraindications are identified, temporary cardiac pacing. In the setting of IE, in which a high-degree heart block is unlikely to be a temporary condition, a transvenous pacemaker is preferable to transthoracic pacing.

There are both early and late indications for surgical intervention in the management of IE. Keeping this fact in mind, the EP should obtain early cardiothoracic surgery consultation if the following conditions are all met: low risk for IE (native valves, immunocompetent, no injection drug use, no comorbid conditions), a stable or subacute manifestation, non-diagnostic findings on TTE, and very well-defined follow-up. Such patients may undergo TEE as an outpatient, and the serial blood culture results can be followed by their personal physicians.

Otherwise, the disposition of all other patients with potential or confirmed IE is driven by the following factors:
• Need for further evaluation (diagnosis or extent of involvement not certain)
• Severity of the illness
• Need for surgical or mechanical support (e.g., mechanical ventilation, intraaortic balloon counterpulsation device)
• Need for intravenous antibiotic therapy
• Reliability of the patient
• Availability of close follow-up

Immediate operative care should be strongly considered if the surgical criteria are met. Patients in critical condition who do not require surgery should be admitted to the intensive care unit. Most other patients with presumed IE can be admitted to a medical service with cardiac monitoring for further evaluation, initiation of intravenous antibiotic therapy, and arrangement for further outpatient care.

REMOVAL OF MEDICAL HARDWARE
Blood culture specimens should be obtained via any long-term indwelling intravascular catheter. These devices should then be removed. Decisions to remove prosthetic valves or pacemaker wires are complex and should be made in consultation with cardiology, cardiothoracic surgery, or infectious disease specialists (or all three).

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION
All patients with suspected or confirmed IE should be admitted to the hospital. The EP might consider discharge from the ED if the following conditions are all met: low risk for IE (native valves, immunocompetent, no injection drug use, no comorbid conditions), a stable or subacute manifestation, non-diagnostic findings on TTE, and very well-defined follow-up. Such patients may undergo TEE as an outpatient, and the serial blood culture results can be followed by their personal physicians.

Endocarditis is not always associated with infection. In some disease states, vegetations composed of bland, platelet-fibrin aggregates may adhere to the endocardium. Eventually, fibrosis of these lesions occurs. These vegetations are usually sterile but may become seeded with infectious organisms. Illnesses associated with nonbacterial thrombotic endocarditis (NBTE) include malignancies, severe burns, hypercoagulable states (e.g., antiphospholipid syndrome and disseminated intravascular coagulopathy), uremia, and connective tissue diseases such as systemic lupus erythematosus. It stands to reason that the clinical manifestations of NBTE are related mainly to embolic phenomena and, occasionally, to valvular dysfunction. Without infectious vegetations, the generalized immune response and the localized destruction and infectious seeding of other organs do not occur. The primary indication for surgical intervention in patients with NBTE is valvular dysfunction, although surgery may be performed to prevent embolic events.
For more than 50 years, the American Heart Association (AHA) has set forth recommendations in an effort to prevent IE. Antimicrobial regimens were recommended for planned, potentially contaminated procedures (dental, respiratory, GI, and genitourinary) in an effort to prevent IE in at-risk populations. Unfortunately, these guidelines lacked good evidence to support their efficacy and were so complex that their implementation was difficult. In April 2007, the AHA released new guidelines in an effort to address these issues.17

Rather than provide prophylaxis to patients at risk for the development of IE, the 2007 guidelines have changed to recommend that antimicrobial prophylaxis be administered only to patients at highest risk for an adverse outcome from IE (Box 62.6), thereby greatly reducing the group of eligible patients. The procedures for which prophylaxis is recommended are listed in Box 62.7 and antimicrobial regimens in Table 62.5.

EPs may encounter difficulty managing the expectations of patients who were previously recommended to receive IE prophylaxis but now are not. The rationale for the changes is the lack of scientific evidence to support the claim that IE prophylaxis is actually effective. In fact, the bacteremia resulting from daily activities such as toothbrushing and eating is more likely to result in IE than is the bacteremia associated with dental procedures. Therefore, even if 100% effective, prophylaxis probably prevents only an extremely small number of cases of IE. The cost of prophylaxis is borne financially and through adverse drug reactions. As a result, the AHA is now emphasizing maintenance of optimal oral health and

**ENDOCARDITIS PROPHYLAXIS**

**BOX 62.6 AHA Recommendations for Prevention of Infective Endocarditis**

Cardiac conditions associated with the highest risk for an adverse outcome from endocarditis for which antibiotic prophylaxis is recommended are as follows:

- **Prosthetic cardiac valves**
- **Previous infective endocarditis**
- **Congenital heart disease (CHD)**
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibits endothelialization)
- **Cardiac valvulopathy in a cardiac transplantation recipient**

*Except for the conditions listed here, antibiotic prophylaxis is no longer recommended for any other form of CHD.

Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.

**BOX 62.7 Emergency Department Procedures Requiring Antimicrobial Prophylaxis Against Infective Endocarditis in High-Risk Patients**

Patients at high risk for an adverse outcome from infective endocarditis (see Box 62.6) should receive antimicrobial prophylaxis (see Table 62.4) for the following procedures:

**Dental Procedures**
- All dental procedures that involve manipulating gingival tissue or the periapical region of teeth or perforating the oral mucosa.
- The following procedures and events do not need prophylaxis: routine anesthetic injections through noninfected tissue, taking of dental radiographs, placement of removable prostodontic or orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips or oral mucosa.

**Otorhinolaryngologic/Respiratory Procedures**
- Any surgical procedure that involves an incision in respiratory mucosa (e.g., peritonsillar abscess incision and drainage, cricothyroidotomy, tracheotomy, tonsillectomy and/or adenoidectomy)
- Bronchoscopy with a procedure that involves an incision in respiratory mucosa

**Minor Surgical Procedures**
- Any surgical procedure that involves infected skin, skin structure, or musculoskeletal tissue (e.g., incision and drainage of an abscess)

NOTE: Prophylaxis for gastrointestinal procedures is no longer recommended.

NOTE: Prophylaxis for genitourinary procedures is recommended only if the patient is known to have enterococcal colonization or urinary tract infection at the time of instrumentation.

Management of Emergencies Related to Implanted Cardiac Devices

Daniel Cabrera and Wyatt W. Decker

KEY POINTS

- Chest compressions should not be performed on patients with an implanted left ventricular assist device who are in cardiac arrest because the device may shear the aorta.
- Major failure of an implanted left ventricular assist device is extremely serious but not catastrophic; patients’ minimal but present cardiac function gives time for temporizing maneuvers.
- Patients who have had a cardioverter-defibrillator implanted and experience multiple shocks per day are deemed to be in electrical storm and should be managed very aggressively for ischemia and electrolyte abnormalities.
- A magnet changes most pacemakers to a continuous, preset rate, usually about 80 beats/min. When a magnet is moved away from a pacemaker, the device returns to the previously programmed, baseline function. Implantable cardioverter-defibrillators may need to be reprogrammed after exposure to a magnet.

INTRODUCTION

The use of implantable devices to support the electrical function of the heart has become widespread since they were first described in the early 1950s. Most recently, the use of ventricular assist devices has become more common in the scenario of an increasing number of patients with severe congestive heart failure (CHF).

Currently, millions of patients in the United States have such implants, and they seek care in emergency departments (EDs) because of complications related to these devices and the conditions that led to the implantation.

This chapter focuses on general concepts and the approach to and management of emergencies related to permanently implanted cardiac devices, specifically, pacemakers (PMs), implantable cardioverter-defibrillators (ICDs), and left ventricular assist devices (LVADs).

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

An ICD is the first line of therapy for prevention of sudden cardiac death, which is commonly the result of ventricular fibrillation (VF) or ventricular tachycardia (VT). The first internal defibrillator was implanted in 1980 by Mirowski and Mower. Since then, the technology and indications have grown enormously. More than 120,000 devices are implanted in the United States every year. Given this scenario, emergency physicians (EPs) face a growing number of patients with increasing complexity who are arriving at EDs with ICD-related complaints.

GENERAL CONCEPTS OF FUNCTION

Current ICDs correspond to third-generation devices, which are small (40 mL) and reliable and contain sophisticated electrophysiologic analysis algorithms. They can store and report a large number of variables, such as electrocardiograms (ECGs), defibrillation logs, energies, lead impedance, and battery charge. ICDs are usually implanted in the left infraclavicular area via a transvenous technique.

The ICD unit consists of a case containing the battery, circuitry, and pulse generator; a right ventricular apex lead for sensing and defibrillation; and an atrial lead. Current devices for biventricular pacing can be equipped with a coronary venous lead. The diagnostic and treatment functions are configured during placement of the device, along with determination of the defibrillatory threshold (DFT) necessary for the specific patient. Typically, the ICD is set to deliver energies 5 to 10 J above the DFT. According to these specifications, the battery life of the modern lithium-silver-vanadium device is approximately 8 years but depends largely on the frequency of the shocks delivered. Most of the devices are equipped with a patient alert system that prevents clinically significant battery-related complications.

The algorithmic criteria for delivering a shock are based largely on the rate, duration, polarity, and waveform of the signal sensed. When the ICD detects atrial and ventricular electrical signals that fulfill the preprogrammed criteria for VT or VF, the device decides the appropriate tier of treatment, which can be:
• Antitachycardia pacing, generally for monomorphic tachycardias
• Low-energy defibrillation (±2 J synchronized with the R wave)
• High-energy defibrillation in which the shocks are delivered as a biphasic wave

These treatments can be felt by the patient as sensations varying from discomfort to frank pain.\(^6\)

Approximately 50% of the patients will experience an ICD discharge in the first 2 years of use. To lower the incidence of ventricular and supraventricular arrhythmias, a considerable proportion of these patients receive adjunctive pharmacologic therapy, usually with amiodarone, sotalol, and statins.\(^4\)

After the ICD delivers a shock, three scenarios are possible: successful defibrillation, continuation of the VT or VF, or conversion to another rhythm—usually pulseless electrical activity (PEA) or asystole. After an efficacious shock, the patient’s heart returns to a previous stable rhythm. If the patient continues in VT or VF, the device delivers five more rescue shocks, after which it reanalyzes the waveform.\(^6\) In case of postdefibrillation (or primary) bradycardia or asystole, the ICD can display antibradycardiac features similar to those of a VVI PM.

Up to 25% of patients can experience an inappropriate shock, defined as a shock delivered for a rhythm different from sustained VT or VF. The most common causes of inappropriate shocks are supraventricular tachycardias (e.g., atrial fibrillation, paroxysmal supraventricular tachycardia, sinus tachycardia), which are read as VT.\(^5\) Another common cause is misreading of T waves as part of the QRS complex, thereby duplicating the sensed rate. Occasionally, the leads can suffer mechanical damage, such as insulation defects or lead fracture, and such damage can cause electronic noise to be mistakenly detected as VT or VF. These problems are partially solved in modern “noncommitted” apparatuses, which can reanalyze the appropriateness of the rhythm after charging but before shocking.\(^7\)

Currently, no evidence has shown that the electromagnetic fields from daily life artifacts can interfere significantly with defibrillators. However, it is recommended that patients with ICDs avoid placing their cell phones closer than 15 cm to the device and avoid long exposure to metal detectors or antitheft devices.\(^7\) Some medically related sources of interference such as electrocauterries can cause significant malfunction; therefore, interrogation of the device after exposure is recommended.\(^8\) Magnetic resonance imaging (MRI) is contraindicated in patients with ICDs given the risk for mechanical torque, thermal injury, and deprogramming.

**PATIENT TEACHING TIPS**

**Implantable Cardioverter-Defibrillator**

The occurrence of more than one shock makes urgent medical attention mandatory; the patient should call 911. If the ICD is firing, the patient must avoid driving.

The patient should always carry the identification card for the ICD, as well as contact information (emergency phone number) for the treating cardiologist.

Pain or swelling in the pocket area could be a sign of infection; the patient should seek medical care as soon as possible.

It is recommended that a cell phone not be placed closer than 15 cm from the ICD and that the patient not linger in metal detectors or antitheft devices.

**INDICATIONS FOR PLACEMENT OF AN IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR**

The major and commonly accepted indications for use of an ICD are summarized in Box 63.1. In recent years the indications and uses have expanded such that the current published guidelines have been outpaced.\(^10\) Multiple trials showing a significant reduction in sudden cardiac death have been followed by publications with similar results regarding primary prevention in selected populations with structural heart disease and a low ejection fraction, as well as in other populations with specific cardiac abnormalities.

**APPROACH TO COMPLICATIONS RELATED TO THE IMPLANTATION PROCEDURE**

During the early days of ICDs, with their large abdominal cases and pericardial leads, the morbidity and mortality associated with the procedure were considerable. With later use of the transvenous technique, the perioperative mortality rate for ICD placement is less than 0.8%.\(^4\) Nevertheless, infectious, lead-related, thromboembolic, and mechanical complications can occur.

The rate of pocket or lead infection has been reported to be between 2% and 7%.\(^11\) The most common pathogens are cutaneous flora, usually *Staphylococcus aureus* and *Staphyloccucus epidermidis*. During the first year after ICD implantation, infections related to the device are primarily due
to the procedure; after that period they are probably due to secondary seeding. From a clinical perspective, common infectious signs and symptoms in patients with ICDs are notoriously absent and patients may have only vague complaints. Infections of the case and leads have a wide incidence of about 1% to 12%. Diagnosis of a delayed hardware infection requires a high index of suspicion given the absence of a definitive or proven hardware infections require contact with the implant team for placement of an implantable cardioverter-defibrillator.5,11

Modern lead systems are extremely reliable but are still prone to fracture, malposition, dislodgment, and damage to the insulation. These defects commonly lead to electrical noise that can precipitate inappropriate shocks. In the evaluation of a patient with suspected lead malfunction, a chest radiograph is required for confirmation of proper positioning and integrity of the leads.4,7,11 Contacting the implant team for replacement of the lead is the only alternative possible for hardware failure. Problems related to the battery, pulse generator, and circuitry are extraordinarily rare. Thromboembolic complications can be seen in as many as 30% of patients with ICDs; they usually involve the cephalic and subclavian veins and do not generally lead to ICD malfunction. Affected patients exhibit unilateral arm swelling, pain, discoloration, and paresthesias, which require evaluation with ultrasonography, venography, or computed tomography. Standard treatment with heparin and warfarin usually results in a good outcome.11

The many mechanical complications related to placement may be manifested early or in delayed fashion. A considerable number of patients experience some degree of tricuspid regurgitation, with approximately 10% of cases being clinically significant. In addition, there is a theoretic risk for fibrosis of the apical lead, which could increase the DFT and make the shocks ineffective. Later manifestations with life-threatening mechanical complications, such as cardiac perforation, cardiac tamponade, hemothorax, pneumothorax, and air embolism, are very rare.11

**APPRAOCH TO PROBLEMS RELATED TO FUNCTION AND DYSFUNCTION**

In a patient with complaints related to functioning of the ICD, the EP must consider that the majority of such patients have severe structural heart disease with a poor ejection fraction and that most of them are in end-stage CHF. They can have a myriad of symptoms; however, these symptoms can be approached systematically (Box 63.2). Evaluation of a patient with an ICD must start by placing the patient in a monitored setting with external defibrillator capacity.3,12

**Cardiac Arrest**

Causes of death in this population are PEA after VT or VF (29%), defibrillation failure (26%), primary PEA (16%), and refractory VT or VF (13%).12 When a patient is seen in VT- or VF-related cardiac arrest, the most likely scenario is that VT or VF occurred and the ICD correctly sensed and delivered the shocks but failed to achieve defibrillation. It is critical for the EP to recognize and treat correctable causes of VT and VF. Common causes in this population are ongoing ischemia, electrolyte disturbances (especially hypokalemia and hypomagnesemia), and the arrhythmic effect of drugs.4 Many such patients have non–VT/VF-associated cardiac arrest in the context of end-stage CHF; in these cases, disabling the device could be helpful in the resuscitative efforts. Disabling can be accomplished by placing a magnet over the surface of the case pocket. It is very important to remember that after a magnet is placed over the device, it must be assumed that the device is permanently disabled and reprogramming is needed. Standard advanced cardiac life support (ACLS) protocols must be followed both for VT/VF- and non–VT/VF-related causes of cardiac arrest, the only difference being that the external defibrillator paddles and patches should not be placed directly over the ICD case.

Unstable with Ongoing Shocks

Management of an unstable patient must be based on the functioning of the ICD. Basically, this situation may represent two scenarios:

- Inappropriate shocks leading to hemodynamic compromise
- Refractory VT with a pulse and delivery of multiple inappropriate shocks

Patients can experience cardiovascular collapse caused by repetitive inappropriate shocks secondary to true or misdiagnosed supraventricular tachycardias. In such cases, treatment must start by decreasing the rate of the tachycardia with the usual pharmacologic treatment (e.g., beta-blockers, calcium channel blockers). If these measures fail, the next step is to disable the ICD. A considerable proportion of patients arrive at the ED in unstable bradycardia; in this setting the VVI function of the device will be helpful, but prompt recognition of the cause (commonly end-stage CHF) and standard ACLS treatment are mandatory. 7

Those with sustained VT with a pulse and appropriately shocked by the device represent an in extremis population. The most critical intervention is the delivery of higher-energy shocks with an external defibrillator (regardless of whether the ICD is disabled) and rapid correction of the cause of the VT. 8

Both populations require mandatory electrophysiologic consultation and interrogation of the device.

Electrical Storm

Electrical storm is commonly defined as more than two therapies (antitachycardia pacing or shocks) delivered in a 24-hour period. 1 It is believed to affect about 10% of patients with ICDs 3 and is a common complaint in these patients. 8 Classically, such patients are rather stable but complain of several shocks delivered in the preceding hours. The significance of electrical storm is that it is usually a herald of life-threatening acute pathology, commonly acute cardiac ischemia, hyperkalemia, and decompensated CHF, thus placing these patients at immediate high risk for death.

Management starts with standard stabilization and cardiac monitoring followed by correction of any obvious abnormalities, evaluation for mechanical failure, device interrogation, electrophysiologic consultation, and aggressive management of CHF and acute ischemia.

Stable with a Recent Isolated Shock

The most important first step is to determine whether the shocks were appropriate. 4 The patient should be placed in a monitored setting where the heart rhythm can be recorded, followed by a chest radiograph to evaluate for possible hardware failure (e.g., lead fracture) and basic laboratory tests to look for ischemia or electrolyte disturbances. Any signs or symptoms around the moment of the shock (e.g., chest pain, shortness of breath, chest trauma) should be noted. It is also important to inquire about new drugs or changes in dosage (especially for amiodarone). Arrhythmias discovered during monitoring, as well as metabolic causes of VT or VF, must be treated in the usual fashion.

Occasionally, patients complain of hearing a beep from the device. Some models can emit a beep in the event of battery discharge or another cause of malfunction. Stable patients with an isolated shock require interrogation of the ICD so that the underlying rhythms can be evaluated and the ICD can be reprogrammed. 4 The decision for hospital admission is usually made jointly by the EP and the electrophysiologist based on the appropriateness of the shock, the availability of follow-up, and the overall clinical status of the patient. Patients who have experienced isolated appropriate shocks but have no change in cardiopulmonary status, no evidence of ischemia, and no electrolyte abnormalities can be discharged from the ED for follow-up with an electrophysiologist. 14

Stable with Other Cardiorespiratory Symptoms

Patients can come to the ED with cardiorespiratory complaints not clearly related to ICD functioning, such as chest pain, shortness of breath, and dizziness. Evaluation and interrogation of the ICD are advisable to ensure that the symptoms are not related to device malfunctioning. Further management is focused on the patient’s complaint once information from the device has been gathered.

### PRIORITY ACTIONS

**Implantable Cardioverter-Defibrillator**

Patients with ICD-related complaints must have prompt transport by emergency medical services to the closest emergency department. Always place a patient with an ICD in a monitored bed. In the case of a disabled or malfunctioning ICD, the defibrillator patches must be placed in the anteroposterior position during monitoring and away from the ICD pocket. Gather focused clinical and technical information about the device, and contact the electrophysiologist taking care of the patient. Obtain an anteroposterior chest radiograph and measurements of cardiac biomarkers and serum electrolytes. The patient will most probably need admission to a unit with a monitored bed.

### RED FLAGS

**Implantable Cardioverter-Defibrillator**

- Multiple shocks probably represent electrical storm, which confers high risk for an adverse outcome in the patient.
- Chest pain before ICD discharge can be a sign of ischemia leading to ventricular tachycardia or ventricular fibrillation.
- Amiodarone and class I antidysrhythmic agents raise the defibrillatory threshold, and recent changes in the dose or interactions with other medications can cause failure of ICD defibrillation.
- A history of syncope may represent successfully treated ventricular tachycardia or fibrillation.
LEFT VENTRICULAR ASSIST DEVICES

LVADs were initially developed more than 25 years ago as intermediate treatments to “bridge” patients to heart transplantation. In this chapter the discussion pertains particularly to permanent devices such as the WorldHeartNovacor, HeartMate VE, and HeartMate XVE.

Currently, more than 5 million Americans are estimated to suffer from heart failure with an aggregate 5-year survival rate of 50%. The high mortality and poor quality of life in patients with late-stage heart failure has led to further study and proposed uses for LVADs; the device has now been approved as a therapy for candidates waiting for a heart transplant (bridge therapy) and for patients with end-stage heart failure who are not candidates for heart transplantation because of age or other medical comorbid conditions, known as destination therapy. Currently, nearly a thousand patients have undergone implantation of an LVAD as destination therapy for severe heart failure, but an estimated 30,000 to 60,000 patients per year could be eligible for the procedure.

GENERAL CONCEPTS OF FUNCTION

LVADs are battery-operated, mechanical or electric pumps that are surgically implanted to help maintain and augment the pumping ability of the heart. Increasing problems with limited organ availability for transplantation and greater numbers of patients with heart failure have expanded the use of these devices.

Conceptually, the device consists of a stroke-volume generator pump, an outflow tract efferent from the left ventricle, an inflow tract afferent to the ascending aorta, and a battery support system. The pump mechanism is implanted into the upper part of the abdomen or lower part of the thorax, and a skin-tunneled driveline connects with the exterior to permit electrical connections and pneumatic venting.

Originally, most models consisted of mechanical pumps, which were diaphragm oscillators that generated pulsatile blow flow through the outflow tract. Current devices work on axial pump flow in which electromagnetic centrifugal or rotary engines generate nonpulsatile flow; this translates to no pulse or a very faint pulse when examining such patients. These newer axial flow pumps confer several benefits such as smaller pumps and drivelines, fewer moving parts, and more efficient use of energy. Among their disadvantages are the requirement for systemic anticoagulation and the lack of a backup method (e.g., the hand-operated pump in older models) when device failure occurs.

INDICATIONS FOR PLACEMENT OF A LEFT VENTRICULAR ASSIST DEVICE

Indications for LVAD placement can be categorized according to therapeutic goals (Box 63.3). Patients awaiting cardiac transplantation and those with New York Heart Association class IV heart failure (and who are ineligible for transplantation) are candidates for LVAD implantation. The Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial compared patients with optimal medical management alone and those with medical management and implantation of a HeartMate VE LVAD. The study, conducted over a period of 2 years, showed a relatively lower risk for death (48%) during the follow-up period in the LVAD group than in the medical management group. The Food and Drug Administration approved the LVAD device in 2002 as destination therapy for patients with heart failure. Further follow-up has continued to show better survival in LVAD recipients, as well as improved quality of life.

BOX 63.3 Categories of Indications for Placement of a Left Ventricular Assist Device

- Bridge to recovery (e.g., severe left ventricular dysfunction secondary to a reversible cause such as myocarditis)
- Bridge to transplantation
- Destination therapy (patients with end-stage congestive heart failure who are not candidates for transplantation)
Infections
Infectious complications of the LVAD components are common, about 6 per 1000 device-days. The signs and symptoms can be deceiving given the paucity of classic infections. Pain located near the case or driveline is often a sign of hardware infection. Patients in whom such infections are suspected must be admitted to the hospital for intravenous antibiotic therapy under the care of the implantation team. Frequently, débridement and mobilization of the components (e.g., the driveline) must be performed.

Minor Device Failure
Minor device failure is a broad category related to malfunction of the hardware apart from the pump. Commonly, the patient has a nonfunctioning device secondary to a discharged battery or an external circuitry error. In older mechanical models, the pumping function of the LVAD can be supported manually until the battery or the control panel can be replaced. Before discharge from the hospital all patients undergoing LVAD implantation and their family members are taught how to disengage the device and attach a hand pump to continue blood flow through the LVAD. The hand pump should be carried with the patient at all times. Information about how to engage the hand pump system can be found on websites for each of the devices.

Current models have the ability to alert patients when electrical and battery issues are diagnosed, which usually leads to an ED visit. In both situations just described, the implantation team should be contacted to evaluate the device. Usually, these issues do not lead to explantation of the device.

Major Device Failure
A life-threatening emergency, major device failure is caused by outflow or inflow disconnections, flow valve problems, or pump failure, and patients are commonly initially seen in cardiogenic shock or cardiac arrest. The catastrophic nature of such an event requires prompt and aggressive cardiac life support and emergency consultation with the cardiovascular surgical team. The use of vasoactive drugs and intraaortic balloon pump support constitute the basis of management. Troubleshooting of device failure by nonexperienced physicians is extremely complicated and discouraged. Patients with an LVAD characteristically have a severely low but measurable ejection fraction. The remnant systolic function is often enough to keep the patient alive until temporizing measures can be instituted. Aggressive management of cardiogenic shock and immediate involvement of the implantation team are mandatory.

Thromboembolic and Bleeding Events
Patients usually require systemic anticoagulation with an international normalized ratio of 2.5 to 3.0 and aspirin for antiinflammatory purposes. Those experiencing thromboembolic complications such as a cerebrovascular accident and peripheral embolism will benefit from standard treatments. Of note, there is no clear evidence related to the use of thrombolysis in this population; however, the risks appear to outweigh the benefits, and close discussion and planning among emergency medicine, thoracic surgery, and neurology are essential.

In patients who are bleeding, the cardiovascular team must be contacted before reversal of anticoagulation. Caution must be exercised in volume resuscitation of such patients given the tenuous function of the ventricles. Management does not differ significantly from that for the regular population.

BOX 63.4 Categories of Complications of Left Ventricular Assist Devices
- Thromboembolic and bleeding events
- Infections
- Minor device failure (e.g., battery dysfunction)
- Major device failure (e.g., outflow tract disconnection, pump failure)

APPROACH TO PROBLEMS RELATED TO FUNCTION AND DYSFUNCTION
As growing numbers of patients are undergoing LVAD implantation, it will be important for EPs to understand the major complications of these devices. Problems with LVADs can be divided into four broad categories (Box 63.4).

Hardware malfunction is not uncommon and can occur at a combined rate of about 0.87 events per patient per year. The incidence of life-threatening hardware failure can be as high as 7.8% during the implantation period, often related to pump or inflow valve problems. Because these patients are in extremis, it is paramount for the EP to know that chest compressions should almost never be performed in patients with an LVAD because the trauma from the compressions can shear the outflow tract from the aorta and cause massive hemorrhage. ACLS protocols can otherwise be followed during resuscitation of patients with an LVAD.

RED FLAGS
Left Ventricular Assist Device
Local pain in the pocket or driveline may herald infection. Signs and symptoms of right-sided heart failure can indicate device malfunction. Look for evidence of thromboembolic disease, and proceed with standard management.

Thromboembolic and Bleeding Events
Patients usually require systemic anticoagulation with an international normalized ratio of 2.5 to 3.0 and aspirin for antiinflammatory purposes. Those experiencing thromboembolic complications such as a cerebrovascular accident and peripheral embolism will benefit from standard treatments. Of note, there is no clear evidence related to the use of thrombolysis in this population; however, the risks appear to outweigh the benefits, and close discussion and planning among emergency medicine, thoracic surgery, and neurology are essential.

In patients who are bleeding, the cardiovascular team must be contacted before reversal of anticoagulation. Caution must be exercised in volume resuscitation of such patients given the tenuous function of the ventricles. Management does not differ significantly from that for the regular population.

Infections
Infectious complications of the LVAD components are common, about 6 per 1000 device-days. The signs and symptoms can be deceiving given the paucity of classic infections. Pain located near the case or driveline is often a sign of hardware infection. Patients in whom such infections are suspected must be admitted to the hospital for intravenous antibiotic therapy under the care of the implantation team. Frequently, débridement and mobilization of the components (e.g., the driveline) must be performed.

Minor Device Failure
Minor device failure is a broad category related to malfunction of the hardware apart from the pump. Commonly, the patient has a nonfunctioning device secondary to a discharged battery or an external circuitry error. In older mechanical models, the pumping function of the LVAD can be supported manually until the battery or the control panel can be replaced. Before discharge from the hospital all patients undergoing LVAD implantation and their family members are taught how to disengage the device and attach a hand pump to continue blood flow through the LVAD. The hand pump should be carried with the patient at all times. Information about how to engage the hand pump system can be found on websites for each of the devices.

Current models have the ability to alert patients when electrical and battery issues are diagnosed, which usually leads to an ED visit. In both situations just described, the implantation team should be contacted to evaluate the device. Usually, these issues do not lead to explantation of the device.

Major Device Failure
A life-threatening emergency, major device failure is caused by outflow or inflow disconnections, flow valve problems, or pump failure, and patients are commonly initially seen in cardiogenic shock or cardiac arrest. The catastrophic nature of such an event requires prompt and aggressive cardiac life support and emergency consultation with the cardiovascular surgical team. The use of vasoactive drugs and intraaortic balloon pump support constitute the basis of management. Troubleshooting of device failure by nonexperienced physicians is extremely complicated and discouraged. Patients with an LVAD characteristically have a severely low but measurable ejection fraction. The remnant systolic function is often enough to keep the patient alive until temporizing measures can be instituted. Aggressive management of cardiogenic shock and immediate involvement of the implantation team are mandatory.

Infections

In patients who are bleeding, the cardiovascular team must be contacted before reversal of anticoagulation. Caution must be exercised in volume resuscitation of such patients given the tenuous function of the ventricles. Management does not differ significantly from that for the regular population.
PACEMAKERS

In 1952 a PM became the first electronic implantable device when it was used to treat a patient with a high-degree block. A few years later, PM use became widespread for treating myriad conditions, from sick sinus rhythm to cardiac resynchronization. Now, millions of Americans have an implanted PM, with an estimated 425 new PMs per 100,000 people per year.25

GENERAL CONCEPTS OF FUNCTION

A PM has two basic components: a pulse generator (which also contains analyzing hardware and firmware) and the lead or leads. Conceptually, the device senses the intrinsic activity of the heart, atrial or ventricular, and after processing the information with the preprogrammed algorithm, decides if it is necessary to initiate a myocardial depolarization.

PMs have evolved and become more complex in recent years. A five-digit code system to describe function was developed by North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group.26 It explains the sensing and pacing abilities and the expected actions (Table 63.1). Currently, the most common pacing modes are AAI, VVI, and DDD.

It is of cardinal importance that EPs understand the representation of the PM activity on the surface ECG. The triggering activity of the device is able to be visualized as a spike (also known as an artifact) on the ECG. These spikes will usually precede the atrial or ventricular activity. Older models are commonly monophasic and produce a conspicuous electrical spike on the surface tracing; however, modern devices are biphasic, which produces an artifact that is considerably smaller and can sometimes be very difficult to appreciate. In this scenario, recording of the ECG at higher amplitude (i.e., to increase to size of the QRS complex) may be helpful to appreciate the artifact. In cases in which failure to pace is suspected (see later), it may be helpful to place a magnet over the PM case, which will turn the device into an asynchronous mode, commonly VV, and make assessment easier. Extreme caution is necessary in patients who are dependent on the PM.

The surface ECG will show a left bundle branch block as the electric stimulus is arising from the right ventricle. It is important to remember that the QRS complex will be discordant from the ST segment.

### TIPS AND TRICKS

**Pacemaker**

Understand pacemaker nomenclature (see Table 63.1). Look for the presence of pacemaker spikes on the electrocardiogram; they can be very subtle or, rarely, not visible. The presence of a bundle branch block pattern on the electrocardiogram should alert the clinician to the possibility of a paced rhythm.

Know how and when to use a magnet.

### PATIENT TEACHING TIPS

**Pacemaker**

Discuss the importance of regularly scheduled checkups for the device, as well as the patient. Warn of possible interference with device by medical imaging and procedures. Highlight the importance of carrying device information all the time.

### INDICATIONS FOR PLACEMENT OF A PACemaker

There are many indications for PM placement, some of which are widely accepted whereas others are more controversial. Common indications include patients with high-degree atrio-ventricular block, symptomatic blocks, and sick sinus rhythm. Recent years have seen an increase in the use of dual-chamber PMs for cardiac resynchronization in patients with heart
failure. Box 63.5 contains a summary of class I indications for PM placement.

**APPRAOCH TO COMPLICATIONS RELATED TO THE IMPLANTATION PROCEDURE**

The complications related to placement of a PM are similar to those described for ICDs; the most significant are infections, thromboembolic disease, and tricuspid valve regurgitation.

Infections have an incidence of about 1.9 events per 1000 device-years.28 Signs and symptoms such as malaise, pocket pain, or swelling may indicate infection. It is recommended that blood be collected for culture and broad-spectrum antibiotics be initiated with a focus on cutaneous flora. Admission and consultation with the primary electrophysiologist are recommended.

Thromboembolic disease is manifested similar to other causes, including pain, swelling, vein distention, and shortness of breath. Treatment does not differ from that for standard venous thromboembolism and rests on the use of anticoagulants. The decision to perform lead change or explantation is not an emergency, and it is usually done at the discretion of the implantation team.29

The incidence of tricuspid regurgitation after PM placement is relatively low. Fifty percent of these patients will have right heart failure, whereas others may remain asymptomatic. Valve replacement or annuloplasty is sometimes required.30

**Box 63.5** Class I Indications for Placement of a Pacemaker

1. Third-degree and advanced second-degree atroventricular (AV) block at any anatomic level and associated with any of the following conditions:
   a. Bradycardia with symptoms (including heart failure) presumed to be due to AV block (level of evidence: C)
   b. Arrhythmias and other medical conditions requiring drugs that result in symptomatic bradycardia
   c. Documented periods of asystole of 3.0 seconds or longer or any escape rate less than 40 beats/min in awake, symptom-free patients (levels of evidence: B, C)
   d. After catheter ablation of the AV junction (levels of evidence: B, C)
   e. Postoperative AV block that is not expected to resolve after cardiac surgery (level of evidence: C)
   f. Neuromuscular diseases characterized by an AV block, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy (limb-girdle), and peroneal muscular atrophy, with or without symptoms, because of the potential for unpredictable progression of AV conduction disease (level of evidence: B)

2. Second-degree AV block regardless of the type or site of block and with associated symptomatic bradycardia (level of evidence: B)

**APPRAOCH TO PROBLEMS RELATED TO FUNCTION AND DYSFUNCTION**

PM emergencies can be broadly divided into the following categories (Box 63.6):

1. Failure to capture, in which the pulse generator is sending an appropriate electrical impulse but it is not resulting in a heartbeat
2. Failure to pace, in which the device is not generating an electrical impulse
3. Failure to sense, in which the pacemaker is firing inappropriately despite a normal cardiac rhythm
4. Pacemaker-induced tachycardia

The manifestation of PM-related emergencies varies from asymptomatic (e.g., found to be defective on a routine ECG) to full cardiac arrest. Intermediate findings, including palpitations, anxiety, and light-headedness, are common.

Patients with suspected PM malfunction should be connected to a cardiac monitor and undergo evaluation with a 12-lead ECG. This latter step will be of key importance in assessing the cardiac rhythm and identifying any malfunction. It is also recommended that a chest radiograph be obtained for evaluation of mechanical lead problems (e.g., fracture, dislodgment). General laboratory evaluation is likewise warranted given that electrolyte abnormalities and ischemia may increase the depolarization threshold of the myocardium and lead to failure to capture (see the next section).

The majority of PMs are equipped with a magnetic switch that will put the device into synchronized pace mode at a set rate (typically 80 or 100 beats/min). A ring magnet made for this purpose should be held over the pulse generator. Although device-specific magnets are available, any PM magnet will usually suffice. In patients with symptomatic native bradycardia, placement of a magnet may be lifesaving, and it should be maintained until the permanent PM is repaired or a temporary transvenous PM has been placed.

**Failure to Capture**

Failure to capture is defined as the PM being able to sense and deliver an electric stimulus but the electric current fails to elicit myocardial depolarization. Classically, PM spikes are present, but no atrial or ventricular activity follows (Fig. 63.1). Potential causes include lead dislodgment or malposition31 and inflammation at the electrode tip; as mentioned previously, a chest radiograph can assist in assessing lead location and damage. Similar to the previous scenario, the patient will have symptoms of the underlying disease. Standard ACLS management is recommended, in addition to consideration of a transcutaneous PM in patients dependent on a PM.

**Box 63.6** Categories of Pacemaker Emergencies

- Failure to pace
- Failure to capture
- Failure to sense
- Pacemaker-induced tachycardia
**Failure to Pace**

This type of failure is characterized as the PM being able to adequately sense but does not deliver an electric stimulus when it should do so. In failure to pace, PM spikes are absent from the ECG despite an abnormal or slow native rhythm. Causes include lead fracture, battery depletion, failure of the pulse generator, and most commonly, oversensing. Frequently, the scenario is defined as the sensing element of the PM being confused by other electrical signals such as muscular electrical activity, electrical noise, or ventricular signals. The device inappropriately recognizes these signals as atrial in nature and decides to inhibit the delivery of an electric impulse. Failure of the pulse generator can result from an internal malfunction, blunt trauma, and a number of iatrogenic causes, including MRI, radiation therapy, and electrocautery.

Patients will have signs and symptoms related to the underlying disease, commonly with bradycardic rhythms and high atrioventricular blocks. Management consists of standards ACLS bradycardia management followed by interrogation and reprogramming of the PM. Use of a magnet may be helpful in converting the device into an asynchronous mode, thereby potentially bypassing the effect of oversensing.

**Failure to Sense**

Failure to sense occurs when the PM delivers an electric stimulus regardless of appropriate native cardiac activity. It can be caused by lead dislodgment, lead fracture, development of scar tissue at the site of the lead contact, battery depletion, or an unusually low-amplitude cardiac signal. Evaluation of this type of PM failure is very difficult because the ECG will give limited information.

Patients will have the signs and symptoms of CHF. In patients with no obvious trigger to CHF exacerbation, the possibility of PM undersensing must be considered. Device interrogation is highly recommended because information will be obtained about functioning of the device and will potentially be helpful in reprogramming the PM with the necessary new settings.

**Pacemaker-Induced Tachycardia**

Rarely, patients will experience PM-induced tachycardia, also known as runaway PM syndrome. This condition is seen most

---

**Fig. 63.1** Electrocardiogram depicting failure to sense and failure to capture.
often with older, dual-chamber PM models. The cycle is initiated by atypical conduction through the heart, such as a retrograde P wave that falls immediately after the preprogrammed refractory period and sets up a reentry circuit in which the PM fires rapid ventricular beats in response to a perceived atrial beat. As PMs have become more sophisticated, this condition has become far less common.323 A magnet is the first-line intervention for PM-associated tachycardia because it may break the rhythm. Should this approach fail in an unstable patient, external pacing and, ultimately, lead exposure and cutting may be needed.
REFERENCES

Syncope

James Quinn

Presenting Signs and Symptoms

The symptoms of syncope can be dramatic. Patients may or may not have a warning, or prodrome, and frequently suffer a fall and have associated trauma. Those with a prodrome frequently experience lightheadedness, diaphoretic warmth, nausea and vomiting, or any combination of these symptoms. Those witnessing the event often fear that the patient has died or was dead for a short period, thus making it an emotionally charged and anxiety-provoking event.

Classification of Syncope

The American College of Physicians lists four major prognostic categories of syncope: neurally mediated, orthostatic, neurogenic, and cardiac; actually, a fifth category (“syncope of unknown cause”) is recognized because in most cases the cause of the syncope remains unknown even after extensive investigation.6,7

Neurally Mediated Syncope

Neurally mediated syncope is syncope associated with inappropriate vasodilation, bradycardia, or both as a result of inappropriate vagal or sympathetic tone.8 It is a benign type of cardiovascular syncope that is often associated with a sensation of increased warmth and may be accompanied by preceding lightheadedness (prodrome) along with sweating and nausea. A slow, progressive onset suggests the subcategory vasovagal syncope. Sweating and nausea do not occur with orthostatic hypotension, which is another cause of syncope preceded by lightheadedness.9

Neurally mediated or vasovagal syncope may occur after exposure to an unexpected or unpleasant sight, sound, or smell; fear or other emotional distress; severe pain; or surgical procedure. It may also occur in association with prolonged standing or kneeling in a crowded or warm place or after exertion. As a result, the vagus nerve is stimulated, which causes reflex bradycardia and vasodilation.

Pathophysiology

Syncope comes from the Greek word synkoptein, meaning “to cut short.” Hippocrates was the first to use the term and describe the symptom.5 Syncope has many causes, but the pathophysiology of the final pathway is the same: hypoperfusion of the cerebral cortex and reticular activating system, which after 8 to 10 seconds of interrupted perfusion causes loss of consciousness; a shorter period results in lightheadedness or dizziness and is referred to as near syncope.
Situational syncope occurs during or immediately after coughing, micturition, defecation, or swallowing via a similar mechanism. Carotid sinus syncope can be associated with neck pressure (shaving, tight collar) or head turning resulting in stimulation of the carotid sinus in the neck.

**ORTHOSTATIC SYNCOPE**
Orthostatic syncope occurs in individuals with documented postural hypotension associated with syncope or symptoms of presyncope. In cases of orthostatic syncope, measurement of blood pressure is recommended, first after the patient is supine for 5 minutes and then after the patient is able to stand for 1 to 3 minutes. A decrease of more than 20 mm Hg in systolic pressure is considered abnormal, as is a drop in pressure below 90 mm Hg independent of the development of symptoms.9

Because orthostatic hypotension occurs in asymptomatic individuals, vital signs are neither particularly sensitive nor specific. In fact, positive orthostatic changes have been documented in up to 40% of asymptomatic patients older than 70 years and in 25% of those younger than 60 years. Similarly, a notable number of children who are asymptomatic have been documented to have orthostatic hypotension.5,10

The most common cause of orthostatic syncope is intravascular volume loss, which may be due to dehydration or bleeding. Orthostatic syncope is not always benign because many patients with serious causes can have this symptom.11

**NEUROLOGIC SYNCOPE**
Neurologic causes of apparent syncope include seizures, transient ischemic attacks, migraine headaches, subarachnoid hemorrhage, and subclavian steal syndrome. Confusion after apparent syncope that lasts more than 5 minutes, tongue biting, incontinence, and epileptic aura suggest a seizure. A significant differential in blood pressure between the two arms suggests subclavian steal or dissection. For neurologic causes to be considered true syncope, they must by definition be transient in nature and result in a return to baseline neurologic function. Thus, loss of consciousness with persistent neurologic deficits or altered mental status is not true syncope. In fact, according to this criterion very few neurologic events (especially strokes or subarachnoid hemorrhage) meet the definition of syncope.

Most cases involving neurologic causes of syncope are easily predicted. In general, when these patients have symptoms suggesting a specific disease process, the need for intervention based on neurologic symptoms is usually obvious. It is not recommended that a routine neurologic work-up be performed in all patients with syncope unless related neurologic symptoms are present. It has been determined that routine neurologic testing and investigation, such as computed tomography (CT), is not cost-effective in patients without neurologic symptoms.12

**CARDIAC-RELATED SYNCOPE**
Cardiac-related syncope is clearly the most dangerous class of syncope, and it can be a harbinger of sudden death. Because patients with documented cardiac syncope have a 6-month mortality rate of greater than 10%, timely and thorough evaluation is warranted.13

Syncope in this class can be caused by many types of arrhythmias (benign and malignant), valvular and ischemic heart disease, and cardiomyopathies. Although it is clear that patients with known cardiac disease and syncope have a significantly increased incidence of cardiac-related death, cardiac disease may not be recognized in many patients with cardiac syncope, and persons with a history of cardiac disease may appear to be very stable. Therefore, depending on the history and age of the patient, a relatively aggressive search for cardiac problems may be necessary. However, the urgency of these investigations and whether they should be done in the ambulatory or inpatient setting (e.g., monitoring) are unclear.

**SYNCOPE OF UNKNOWN CAUSE**
Syncope of unknown cause is the largest category of syncope, with estimates as high as 40%, even with extensive work-up. Some studies have found that after evaluation in the ED, physicians are uncertain of the cause of the syncope more than 50% of the time.14 As a result, many serious cases are initially classified in this category, which causes a dilemma for emergency physicians who must decide whether to admit or discharge these patients. It is this largest group of patients who present the greatest challenge for physicians.

**RECOMMENDED DIAGNOSTIC TESTS**
Ongoing or related symptoms associated with syncope should direct the ED investigation. CT is not indicated for all patients, but one should not ignore associated symptoms, for which a complete work-up should be performed (e.g., CT in patients with associated headache or abdominal pain, urine pregnancy tests in females, ultrasonography in pregnant women, troponin assay and CT angiography in patients with chest pain and dyspnea).

A routine electrocardiogram (ECG) is almost always indicated, as are rhythm strips and monitoring while the patient is in the ED. Any nonsinus rhythms or new changes on the ECG should be a concern. Routine basic laboratory tests in asymptomatic patients are not recommended, and their use should be guided by the history and physical examination. Recent work has focused on the value of brain natriuretic peptide (BNP) as a predictor of risk in patients with syncope.15 BNP may have some utility but requires further consideration before becoming a recommended test. In particular, the value of a single reading and the timing of drawing blood in relation to the event require further work. In addition, although it makes sense that BNP may be helpful because it is a predictor of congestive heart failure (CHF) and structural heart disease, it remains unclear whether it provides any greater value over taking a good history, especially given the added cost of the test.16

**PROGNOSIS**
Perhaps the best investigation of the prognosis of patients with syncope was done by Soteriades et al., who used data from the Framingham study.17 This study assessed the risk for death in a prospective cohort of 7814 patients over a 17-year period. The results were dramatic. Those with documented heart disease and syncope had twice the mortality rate of patients without syncope, and patients with syncope with a neurologic
cause were 50% more likely to die. People with syncope of unknown cause also had a significantly increased risk for death of 30%, whereas those with neurally mediated (vasovagal) syncope had a lower risk. The study clearly shows that the increased risk for death in this group requires further scrutiny, as does ED disposition and management.

Other studies suggest that cardiac-related syncope represents 5% to 40% of the causes of syncope and is associated with a significant increase in mortality. ED management of patients with cardiac symptoms such as chest pain in addition to syncope is obvious; however, of most concern are asymptomatic patients with syncope. The absence of cardiac symptoms is not reassuring because patients can have serious “silent symptoms” (silent myocardial infarction and silent arrhythmia, such as Brugada syndrome) that may not be obviously associated with syncope on initial evaluation. Such patients may not have a history of cardiac disease, and syncope may be the first symptom. Patients with cardiac symptoms and syncope clearly need thorough and timely evaluation and thus in most cases require emergency hospitalization.

Physicians evaluating patients with syncope who are asymptomatic and without a clear cause are faced with the following questions:

1. Is the syncope a symptom indicating that known underlying heart disease is active, unstable, and related to the episode?
2. Is the syncope a symptom of occult underlying heart disease?
3. Is the syncope a symptom of an occult noncardiac life-threatening process (e.g., pulmonary embolism, occult bleeding, transient ischemic attack, subarachnoid hemorrhage)?

To maximize the sensitivity of detecting underlying disease, physicians frequently admit low-risk patients for further evaluation, although the cost-effectiveness and value of such decisions are often questioned. It is this group of asymptomatic patients with syncope who are most likely to benefit from risk stratification strategies to guide disposition decisions.

ACUTE RISK STRATIFICATION IN THE EMERGENCY DEPARTMENT

Martin et al. developed the first risk stratification scheme for patients evaluated in the ED for syncope. The stratification was premised on 1-year prognosis for death or cardiac morbidity. Four predictors of death at 1 year were found: age older than 45 years, history of ventricular dysrhythmias, history of CHF, and abnormal findings on an ECG. A similar study found that an abnormal ECG and history of structural heart disease (primarily CHF) predicted mortality but that a much higher age cutoff (older than 65 years) could predict death at 1 year.

Sarasin et al. developed a risk score for ED patients with syncope. The score was based on three factors associated with increased risk for an arrhythmia: abnormal findings on an ECG, age older than 65 years, and a history of any cardiac disease (primarily CHF).

Finally, Quinn et al. derived and validated a decision rule that addresses short-term risk (7 days) to better determine immediate risk in patients in the ED. Again, a history of CHF and abnormal findings on an ECG were the most important predictors. The decision rule considered all patients with syncope and also determined that shortness of breath, hematocrit higher than 30, and systolic blood pressure greater than 90 mm Hg were important risk factors. Age older than 75 years was found to be sensitive but nonspecific in this cohort and not useful as a predictor.

Others have tried to validate this work with variable success. The key to studies being able to most closely validate the work is using the proper ECG definition, which includes not only new changes on the ECG but also any nonsinus rhythms that are found not only on the ECG but also during monitoring throughout the patient’s ED stay.

Other important prospective risk stratification studies are from Italy. The OESIL study found that age older than 65 years, history of cardiovascular disease, syncope without a prodrome, and ECG abnormalities were risk factors. The EGSmart study found an abnormal ECG, history of heart disease, absence of a prodrome, supine status, palpitations, and effort-related syncope to be risk factors. Finally, the STePS study found ECG abnormalities, concomitant trauma, absence of a prodrome, and male gender to be short-term risks.

Age as a risk factor deserves specific mention because physicians often admit patients with syncope just because of age. For almost all diseases, older people die sooner than younger people, and health problems in general increase with age. Recommending that all people older than 45 years (or even those older than 65 or 75 years) be admitted because this factor predicts 1-year death is impractical. Although it may be sensitive as a predictor, age by itself is a poor discriminator; many younger people have significant illness that puts them at even greater risk. This was demonstrated in a study of the short-term outcomes of asymptomatic patients who had syncope of unknown cause and were older than 50 years; all had benign outcomes. Furthermore, comparison of age solely as a risk versus other risk factors has shown that risk factors perform better than age alone.

In summary, advanced age is a risk, but no practical age cutoff for risk has been established, and it should be considered with other risk factors. In particular, almost every study on risk factors has found that an abnormal ECG, including abnormalities detected on cardiac monitoring, is important, as is a history of cardiac disease, specifically CHF. The lack of a prodrome or vagal symptoms is also important in every study, but one study that looked at its subjective nature found that physicians had poor agreement on the presence of vagal symptoms.

IMPROVED DIAGNOSTIC STRATEGIES IN THE EMERGENCY DEPARTMENT

Some investigators have reported that diagnostic and prognostic ability improve with more invasive testing such as echocardiography. This makes sense in that this procedure may identify patients with structural heart disease and a limited ejection fraction; however, another study found that patients who would benefit from echocardiography could be identified by their history and physical examination and that this procedure may not be cost-effective. Another group in the United Kingdom found that risk stratification could be improved by...
Physicians recommend that patients with evidence of cardiac and neurologic causes of syncope, as well as other serious outcomes diagnosed in the ED, be admitted to the hospital. Admission is also recommended for patients with undifferentiated syncope who have risk factors for adverse outcomes (Fig. 64.1).

Implementing a protocol of more aggressive strategies such as tilt-table testing and echocardiography but noted that such strategies may not be cost-effective or practical in the ED.31

An Italian group thought that diagnosis could be improved just with more aggressive history taking and physical examination.32

Because echocardiography and other invasive tests are not routinely available in the ED 24 hours per day, investigators have started to use observation units to avoid inpatient admission for a select group of intermediate-risk patients evaluated in the ED.33 There appears to be some promise for syncope observation units, with the goal being to move more low- and intermediate-risk syncope patients from the traditional inpatient work-up to a more structured and efficient observation or outpatient work-up.

**GUIDELINES FOR ADMISSION AND DISPOSITION**

Many specialty societies have devised consensus guidelines for admission to the hospital that have focused on the best available data.34,35 The American College of Emergency Physicians recommends that patients with evidence of cardiac and neurologic causes of syncope, as well as other serious outcomes diagnosed in the ED, be admitted to the hospital. Admission is also recommended for patients with undifferentiated syncope who have risk factors for adverse outcomes (Fig. 64.1).

Physicians may consider for discharge asymptomatic, well-appearing patients and those with a negative work-up for associated symptoms. One should remember that many studies show increased risk in patients with nonsinus rhythms, abnormalities on the ECG, a history of CHF (or other significant heart disease), shortness of breath, anemia, persistently low blood pressure, and advanced age. Patients with these risk factors, even though they are asymptomatic and appear to be well, have a high risk for adverse outcomes and should be considered for admission to the hospital, observational status, or aggressive outpatient investigation.

Aortic Dissection

Nima Afshar

SECTION VII VASCULAR DISEASES

Aortic Dissection

Sixty percent of aortic dissections involve the ascending aorta, either alone or with other parts of the aorta; they are referred to as type A in the now standard Stanford classification. The 40% that do not involve the ascending aorta are Stanford type B (Fig. 65.1). This distinction has important prognostic and therapeutic implications.

THE YOUNG PATIENT

About 7% of patients with aortic dissection are young (<40 years) and usually have no history of hypertension or other known medical problems. These patients nearly always have occult structural cardiovascular disease.

The most important structural vascular disease is Marfan syndrome, which has a prevalence of 1 in 10,000 and occurs in all races. Marfan syndrome accounts for half of aortic dissections in patients younger than 40 years. It is caused by an autosomal dominant mutation in the gene for a type of fibrillin, a protein that makes up part of the elastic fibers in connective tissue of the aorta, lens, and periosteum. Patients are typically tall with long digits, scoliosis, pectus excavatum, and visual problems because of lens dislocation (Fig. 65.2, A to C). Most important, however, thoracic aneurysms invariably develop early in life, usually in the ascending aorta. If their aneurysms are not repaired, most patients will die of aortic dissection or rupture.

Other young patients without a history of severe hypertension who are nevertheless at risk for dissection are those with bicuspid aortic valves and those experiencing acute insults such as cocaine use and trauma. A family history of aortic aneurysms and dissection, beyond syndromes usually associated with aortic pathology, is a newly recognized risk factor seen in 10% to 20% of patients with dissection.

PATHOPHYSIOLOGY

The aorta dissects by two possible mechanisms (Fig. 65.3). The classic mechanism is an intimal tear, which is generally transverse and extends through the very thin tunica intima into the tunica media. Under pulsatile force, blood enters a layer of the media and dissects longitudinally and usually in a distal direction. The other major mechanism is rupture of the vasa vasorum, usually of a penetrating branch within the tunica media, with consequent bleeding into the media. Progression

EPIDEMIOLOGY

Aortic dissection is longitudinal cleavage of the aortic wall by blood, which creates a false lumen that may propagate. The disease was first described in detail by Morgagni in 1761. In 1955, with the advent of cardiopulmonary bypass, DeBakey successfully repaired a dissected descending aorta, thereby providing the first cure. The proximal aorta was first repaired and medical management was established in the 1960s, thus setting the stage for the modern approach to this disease.

A patient in the emergency department (ED) whose proximal aorta has dissected has about a 2% chance of dying every hour during the first 12 hours and almost a 50% chance of dying within 48 hours without surgical treatment. Unfortunately, this disease is often difficult to diagnose. A study involving three academic EDs found that the diagnosis was suspected during the initial encounter in only 43% of cases.

The incidence is 3 per 100,000 people per year. A typical large urban ED sees several cases per year. About 1 in 350 patients evaluated in an ED for chest pain has aortic dissection.
then occurs in the same fashion, either with or without secondary tearing through the intima into the aortic lumen. The aorta generally tears near tethering points, where the vessel undergoes the greatest flexion stress during cardiac contractions. Thus the most common location for initiation of dissection is the first few centimeters of the ascending aorta, the next most common being the origin of the descending aorta just distal to the left subclavian artery.

Major complications of aortic dissection, in order of risk for mortality, are (1) rupture through the thin remaining outer wall; (2) proximal propagation, which can cause coronary occlusion, acute aortic regurgitation, or cardiac tamponade (or any combination of such complications); and (3) occlusion or dissection of branch arteries.

Those who suffer dissection are predisposed to it by a weakened aorta, specifically, degeneration of the tunica media, or suffer a hemodynamic or traumatic insult, or both (Table 65.1).7-9 Medial degeneration can be secondary to chronic hypertension, hereditary diseases of elastin (Marfan syndrome) or collagen (Ehlers-Danlos syndrome), hereditary structural abnormalities (bicuspid aortic valve and aortic coarctation), chronic inflammation, and aneurysm of any cause, which increases wall tension according to Laplace’s law.

Hemodynamic stress on the aorta is produced by hypertension and shear force \( (dP/dt)^* \), or the force of blood ejected from the left ventricle. A hypercontractile, tachycardic heart produces the greatest shear force. These factors may contribute to the initiation of dissection and strongly determine whether a dissection propagates. Exacerbations of hypertension, cocaine intoxication, and third-trimester pregnancy are examples of states that can cause hemodynamic stress on the aorta and result in dissection.

Traumatic causes include medical procedures, such as aortic catheterization and cardiac surgery, and deceleration

\[

events (e.g., falls, motor vehicle collisions), although in blunt trauma, aortic rupture is far more common than dissection.

**PRESENTING SIGNS AND SYMPTOMS**

Dissection of the aorta is usually extremely painful, so acute pain is a chief complaint in nearly 95% of cases (Table 65.2). Aortic pain is sudden and maximal at onset, with its intensity often proportional to the length of dissection. The location of pain is midline and, classically, correlates with the location of dissection: dissection of the ascending aorta results in chest pain, dissection of the arch results in neck or jaw pain, and dissection of the descending aorta results in back and sometimes abdominal pain. Thus the pain may migrate as the dissection propagates. However, there is considerable variability in symptoms and major overlapping of symptoms in type A and type B dissections.

The typical patient is 50 to 70 years old with a history of poorly controlled hypertension. He (2:1 male-to-female ratio) has intense chest or back pain (or both) and is likely to describe it as sharp rather than tearing. The pain does not respond to nitroglycerin. The patient is not dyspneic unless suffering from one of the cardiac complications of dissection.

The patient appears to be in obvious pain and often has elevated blood pressure (see Table 65.2). On cardiac examination the emergency physician (EP) may hear a fourth heart sound ($S_4$) because of left ventricular hypertrophy. The patient must be examined for two life-threatening
complications of type A dissection with retrograde propagation: aortic regurgitation and cardiac tamponade. Aortic regurgitation occurs audibly in a third of cases and is manifested as a decrescendo early diastolic murmur, best heard at the left lower sternal border with the patient sitting up, leaning forward, and holding breath at end-expiration; peripheral pulses can be bounding if the pulse pressure is wide. Cardiac tamponade may be manifested as distant heart sounds, but more often tachycardia and jugular venous distention occur and are followed by hypotension; the pulsus paradoxus should be 10 mm Hg higher, and bedside ultrasound will reveal a pericardial effusion.

Peripheral pulses should also be examined. If the false lumen is occluding one of the subclavian arteries, a focal, palpably weak pulse is usually present, a finding specific for aortic dissection. Blood pressure should be measured in both arms—a difference of 20 mm Hg or greater between extremities should alert the EP to the possibility of subclavian occlusion. It must be remembered, though, that nearly 20% of hypertensive patients have a blood pressure differential of at least 10 mm Hg between extremities. Lower extremity pulses should also be evaluated because frank ischemia of the lower extremities occurs in nearly 10% of cases of aortic dissection.

A thorough neurologic examination should be performed. Fifteen percent of patients with aortic dissection have a focal neurologic deficit, and in the setting of severe acute chest or abdominal pain, this finding is also highly specific for the disease. Potential neurologic deficits in patients with aortic dissection include stroke secondary to carotid occlusion, spinal cord syndromes as a result of spinal or intercostal arterial occlusion, and peripheral neuropathy caused by neuronal ischemia or compression of a peripheral nerve by the false lumen.

### ALTERNATIVE PRESENTATIONS

#### Abdominal Pain

Abdominal pain is one of the complaints in about 25% of patients with aortic dissection and is the primary complaint in 5% of patients; such patients invariably have dissection of the descending aorta. The pain is usually midline but can be referred to the flank, frequently on the left. The pain is typically out of proportion to the physical findings.

#### Painless Dissection

About 6% of patients with aortic dissection do not have pain. Half of these patients have previously undergone cardiovascular surgery, which potentially disrupts the thoracic nerves. One third have syncope, 20% have heart failure, and more than 10% have stroke. There are numerous reports of patients with painless spinal cord syndromes as well. In these difficult cases, picking up clues such as a diastolic murmur, pulse deficit, and an abnormal mediastinum on chest radiography is critical to making the correct diagnosis.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Aortic dissection is often manifested as chest pain (in up to 75% of cases in recent large studies). In any patient with chest pain, the EP must think of three difficult diagnoses that are life-threatening: acute coronary syndrome, pulmonary embolism, and aortic dissection. Acute coronary syndrome often causes a pressurelike pain that is more crescendo than sudden; electrocardiography (ECG) frequently shows ischemic changes, and in the absence of complete coronary occlusion, the pain is usually responsive to nitroglycerin. In fact, one distinguishing feature of both pulmonary embolism and aortic dissection is that in the first several hours of either, the pain typically does not resolve. With pulmonary embolism, the pain is generally pleuritic and associated with significant pulmonary symptoms or signs. Other diagnoses to consider are pericarditis or cardiac tamponade, spontaneous pneumothorax, and esophageal rupture.

In one prospective study, the absence of aortic pain (sudden and severe), a pulse or blood pressure differential, and mediastinal or aortic widening on chest radiography had a
sensitivity of 96% for ruling out the diagnosis of aortic dissection. Conversely, the presence of a pulse deficit or a focal neurologic deficit, with positive likelihood ratios of 47 and 33, respectively, markedly raised the probability of aortic dissection.

PATIENTS WITH UNDIFFERENTIATED CHEST PAIN

In patients with aortic dissection, aspirin should be avoided because it could cause excessive surgical bleeding and may raise the risk for aortic rupture. Nitroglycerin, in the absence of beta-blockade, should also be avoided because it could cause reflex tachycardia. Because acute coronary disease is far more common than dissection, many patients with undifferentiated chest pain receive aspirin or nitroglycerin (or both) at the initial encounter from either paramedics or ED caregivers. However, if the patient’s findings strongly suggest aortic dissection, it is prudent to wait until after imaging studies have ruled out the diagnosis before initiating these therapies. Anticoagulation should be avoided if dissection is even being considered.

CHEST RADIOGRAPHY

The chest radiograph classically shows a wide mediastinum, predominantly on the right in patients with dissection of the ascending aorta and on the left with dissection of the descending aorta (Fig. 65.4). The physician’s subjective impression, rather than formal measurements, is the best indicator of whether the mediastinum is wide. A widened mediastinum is not a sensitive indicator of aortic dissection. It probably occurs in about 60% of cases, but some reports note a widened mediastinum in less than 20%. Other abnormalities of the aorta, such as inward displacement of intimal calcification and a double aortic shadow, may be observed. Pleural effusion may also occur, usually on the left.

D-DIMMER

After the history, physical examination, ECG, and chest radiography, the clinician must decide whether aortic dissection is a reasonable possibility (Fig. 65.5). If so, additional testing is required.

Numerous small studies have demonstrated that the serum biomarker D-dimer is useful for excluding the diagnosis. A meta-analysis that included seven studies with a total of 300 patients with dissection found that D-dimer—at the 500-ng/mL cutoff value commonly used for excluding pulmonary embolism—is 97% sensitive for acute aortic dissection. D-dimer is probably inadequately sensitive in patients with subacute manifestations and those with pure intramural hematoma. In acute manifestations in which the pretest probability of dissection is low, it is reasonable to use D-dimer to exclude the diagnosis and forego further testing. If the pretest probability is not low, the manifestation is subacute, or D-dimer levels are elevated, an advanced imaging study is required (Table 65.3). All of the modalities described are highly sensitive (98% to 100%) and specific (95% to 98%) and thus in most cases will definitively rule in or rule out dissection.

COMPUTED TOMOGRAPHY

The diagnostic study of choice is computed tomographic (CT) angiography of the aorta (Fig. 65.6). It is immediately available in most EDs and can be interpreted quickly by a radiologist. It is highly sensitive for dissection, especially as CT
Fig. 65.5  Algorithm for the diagnosis and treatment of aortic dissection. BP, Blood pressure; CT, computed tomography; CXR, chest radiograph; ECG, electrocardiography; ED, emergency department; HTN, hypertension; labs, laboratory tests; TEE, transesophageal echocardiography.

technology advances—in fact, a 2005 study reported that multidetector CT scanning was 100% accurate in patients with suspected acute aortic disease. Moreover, when its results are negative for dissection, CT scanning frequently shows alternative serious disease to explain the patient’s symptoms. In the ED, CT scanning is more readily available than transesophageal echocardiography (TEE) or magnetic resonance imaging (MRI), and most patients (even if somewhat clinically unstable) are able to undergo CT scanning to enable the diagnosis to be made.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Generally performed by a cardiologist, TEE is an alternative technique in patients with renal failure, which is a relative contraindication to CT scanning (Fig. 65.7). TEE is as sensitive as CT scanning for type A aortic dissection but may be slightly less sensitive for type B lesions; TEE has the advantage of assessing the aortic valve and pericardial space for complications of type A dissection. It may also detect focal ventricular wall motion abnormalities suggesting myocardial ischemia as the cause of the patient’s symptoms. Finally,
is suspected or TEE cannot be performed. However, MRI is slow and the patient must remain in the MRI suite, usually far from the ED, which can be risky in the setting of a potentially life-threatening disease.

MAGNETIC RESONANCE IMAGING
MRI is useful in stable patients with renal failure (gadolinium contrast is not required), especially when a type B dissection is suspected or TEE cannot be performed. However, MRI is slow and the patient must remain in the MRI suite, usually far from the ED, which can be risky in the setting of a potentially life-threatening disease.

ANGIOGRAPHY
Conventional angiography of the aorta is invasive and rarely needed for the diagnosis of aortic dissection. A possible exception is rare patients with ST-segment elevation myocardial infarction (MI) in whom aortic dissection is still a concern.

Fig. 65.6  Computed tomography scans of aortic dissection. The first axial scan (A) shows aortic dissection, demonstrated as serpiginous radiolucenties in the ascending and descending aorta. The second scan (B) shows dissection of the aortic arch. (Courtesy Leslie Quint, University of Michigan.)

Unlike CT scanning, TEE usually identifies the exact location of the intimal tear and assesses overall cardiac function, which aids in operative planning and risk assessment. The downside of TEE, especially during off hours, is the difficulty performing TEE on an emergency basis. Nonetheless, cardiothoracic surgeons may request the study even when dissection has already been diagnosed.
In such cases, the interventional cardiologist may perform angiography of the aorta as part of the cardiac catheterization procedure, thereby ruling out dissection without delaying coronary angiography and potential revascularization. However, even in this time-sensitive situation, many cardiologists prefer CT scanning because cannulation of a dissected aorta is not without risk.

**ELECTROCARDIOGRAPHY**

Findings on ECG are usually unremarkable even though the patient reports severe pain. This incongruence is a red flag. Nonspecific findings on ECG in a patient with severe chest pain should alert astute clinicians to consider aortic dissection.

Patients at risk for aortic dissection may have long-term, poorly controlled hypertension. Therefore, ECG might reveal
left ventricular hypertrophy with high-amplitude QRS complexes and typical ST-T strain patterns. Low-amplitude QRS complexes or electrical alternans may occur in the presence of cardiac tamponade.

A minority of patients are found to have ischemic changes on ECG, which can be due to demand ischemia or partial occlusion of a coronary artery. About 5% of aortic dissections completely occlude a coronary artery, predominantly the right coronary artery. The occlusion usually causes an ST-segment elevation myocardial injury pattern in the inferior leads. With any MI, especially an inferior one, the EP should ideally assess the mediastinum and aorta on a chest radiograph before anticoagulants are given and especially before thrombolysis is begun. The patient should be asked specifically about pain radiating to the back, which is uncommon with MI.

### TREATMENT

The main goal of ED care is to identify the disease and then manage the patient’s blood pressure and heart rate to minimize aortic shear force. The goal for systolic blood pressure is 100 to 120 mm Hg, and the goal for the heart rate is a rate lower than 60 beats/min. Note that the blood pressure goal is independent of the patient’s baseline blood pressure, unlike the approach to most hypertensive emergencies. Therefore, the clinician must watch for signs of iatrogenic end-organ malperfusion. Very short-acting antihypertensives should be used and administered as drips to precisely titrate the dose to effect.

Table 65.4 summarizes the intravenous hypertensive agents used for treatment of aortic dissection. Beta-blockers are the first-line antihypertensive agents in patients with aortic dissection because they most effectively reduce...
both blood pressure and shear force (in patients with significant asthma, diltiazem can be used instead). The ideal beta-blocker is esmolol because of its short half-life and thus its titratability. If blood pressure control with beta-blockers is limited by bradycardia or a plateau effect, a second antihypertensive agent may be needed, invariably a vasodilator.

The standard second-line agent is nitroprusside, which is extremely short-acting and universally effective. Fenoldopam, a highly selective dopamine agonist, is another option. To avoid reflex tachycardia (which increases shear force), vasodilators should be started only after the heart rate has been controlled pharmacologically.

A minimum of two peripheral intravenous lines will be needed, along with an arterial line for continuous blood pressure monitoring. If possible, the arterial line should be placed in the right radial artery so that it is less likely to be affected by the dissection occluding the upstream artery.

The EP must remember that because aortic pain is very severe, adequate analgesia with intravenous opioids should be provided. Opioids help reduce blood pressure.

For any thoracic aortic dissection the clinician should consult a cardiothoracic surgeon immediately. Cardiology consultation may be needed as well, either for admission of a patient with type B dissection or for preoperative TEE, if needed, in a patient with type A dissection.

Type A aortic dissection generally requires emergency thoracic surgery because the mortality rate in patients who do not undergo surgery increases hourly and is 50% to 80% at 1 month. Typically, the surgeon excises the segment of aorta containing the intimal tears and replaces it with a graft, often with some dissected aorta left in place. The aortic valve frequently needs to be replaced as well. With surgery, survival of patients with type A dissection is improved remarkably, to greater than 95% at 1 year. Recently, some experts have advocated nonsurgical management for patients with subacute manifestations or a history of aortic valve replacement (both confer a better prognosis) and for patients with acute stroke or severe comorbid conditions (both confer a worse surgical prognosis).

Type B dissection is usually treated medically, with a 90% survival rate at 1 month. Type B dissection that is complicated by persistent pain, uncontrolled hypertension, branch artery obstruction, or aneurysm has traditionally required surgery. However, endovascular stent placement and balloon fenestration have become therapeutic options; malperfusion syndromes can be reversed in the vast majority of cases, and the false lumen can often be obliterated, thus reducing the chance of aneurysm development and other future complications. Mortality appears to be substantially lower (10% to 15%) with stenting than with surgery (25% to 35%) for complicated type B dissection.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

All patients with newly diagnosed aortic dissection should be admitted to the intensive care unit. Patients with type A dissection may go to the operating room first. In the ED, these patients need intensive care unit–level management and should be in a resuscitation bay with a 1:1 nurse-to-patient ratio to ensure adequate monitoring of blood pressure and response to therapy (see the Red Flags box).

**RED FLAGS**

One third of patients seen in the emergency department with aortic dissection do not have chest pain.

Aortic dissection occurs more commonly in winter, even in temperate climates.

Forty percent of patients with dissection have a normal mediastinal width on chest radiographs.

Beware of pseudohypotension, which is a low blood pressure reading caused by occlusion of an extremity by a dissected vessel wall.

Detection of ischemia on an electrocardiogram does not rule out aortic dissection. Always consider dissection in a patient with inferior ST-segment elevation myocardial infarction; most ascending aortic dissections involve the right aortic wall, and occasionally the right coronary artery will be occluded.

Appropriate medical management of confirmed dissection involves dropping systolic blood pressure to 100 to 120 mm Hg regardless of the starting blood pressure.

Abdominal Aortic Aneurysm

Danielle M. Ware-McGee and Melissa Marinelli

**KEY POINTS**

- The word *aneurysm* is derived from a Greek word meaning “widening.” It has further been defined as permanent and irreversible localized dilation of a vessel.
- Abdominal aortic aneurysm (AAA) refers to pathologic widening of the aorta, and AAAs continue to be a significant cause of morbidity and mortality; early diagnosis is the key to reducing mortality.
- The risk for rupture relates linearly to the maximum cross-sectional diameter of the aneurysm, and 4.5 to 5 cm is the generally accepted size when intervention should occur.
- Elective repair of nonruptured AAAs lowers mortality significantly and warrants a high level of vigilance by health care providers to diagnose this condition in its potentially curative stages.
- Many risk factors promote the development of AAAs, but the most important are smoking, male gender, and family history.
- The two current operative approaches for repair of AAAs are open surgery and endovascular repair; the better approach for individual patients depends on several clinical variables and specific patient characteristics.

**EPIDEMIOLOGY**

Finding a unifying definition for abdominal aortic aneurysm (AAA) that encompasses the various classification schemes related to their size, shape, and location is an arduous task. Simplistically, most AAAs occur infrarenally and are defined as an aortic diameter greater than 3 cm, mostly measured in the anteroposterior dimension. Although normal aortic diameter differs between the sexes, it is not substantial enough to warrant changing the size limit of 3 cm that is currently used to characterize a small AAA. Finally, it is important to note that dilation of an aneurysm encompasses the three layers of the vascular wall; otherwise, the dilation is a *pseudoaneurysm*. For the commonly accepted descriptions and locations of most aneurysms, please see Box 66.1.

At present, AAA is the thirteenth leading cause of death in the United States. Once an AAA ruptures, death is a certainty in more than 65% of cases, with some studies reporting mortality rates as high as 90%, thus highlighting the necessity for rapid surgical repair. Low rates of postmortem examination and the high likelihood that some of these deaths have been erroneously attributed to cardiac causes severely hamper gathering true estimates of the prevalence of and mortality associated with ruptured AAAs. Elective repair of an AAA lowers the mortality to less than 5%, so there is an obvious benefit to diagnosing and treating these aneurysms before they rupture. Given that this disease affects 4% to 7% of adults 65 years or older, the onus increasingly falls on physicians to accomplish this task as the population ages.

**PATHOPHYSIOLOGY**

There is abundant research on identification of risk factors that potentiate the development and growth of AAAs (Box 66.2). Besides male gender, age, and hypertension, every study on the subject of AAAs singles out long-term tobacco smoking as the most important risk factor. AAAs develop in tobacco smokers more than four times more frequently than in lifelong nonsmokers. Lederle et al. compared the relative risk for different diseases in long-term cigarette smokers and found that risk for the development of AAAs is fivefold higher than for cerebrovascular disease and threefold higher than that for coronary artery disease. Smoking not only raises the risk for the development of AAAs but also increases the annual growth rate of existent AAAs, with some studies reporting a rate of 2.83 mm/yr in smokers versus 2.53 mm/yr in nonsmokers. However, the exact means by which smoking enhances aneurysm formation remains a mystery.

In addition to tobacco smoking, there are other risk factors. Atherosclerosis is so highly associated with the development and expansion of AAAs that the American Heart Association (AHA) guidelines on the treatment of AAAs mandate that blood pressure and fasting serum lipid values be strictly monitored and controlled in patients with AAAs. The AHA also recommends that smoking cessation interventions be provided to patients with a personal or family history of aneurysms. Despite the importance of atherosclerosis, additional factors are probably present because not every patient with atherosclerosis has an AAA.

Many authorities cite a possible causal link between the development of AAAs and chronic obstructive pulmonary disease (COPD). Researchers blame tobacco smoking–induced elastin degradation for this proposed association. A review of the literature notes that patients with COPD undergoing long-term treatment with corticosteroids have a much...
BOX 66.1 Aneurysm Classification—Description versus Location

**Description**
Fusiform aneurysms are circumferential with respect to the artery. Saccular aneurysms affect only part of the circumference. Inflammatory aneurysms demonstrate extensive perianeurysmal and retroperitoneal fibrosis, as well as dense adhesions to neighboring organs, which frequently causes ureterohydronephrosis.

**Location**
Juxtarenal aneurysms arise distal but in very close proximity to the renal arteries. Pararenal aneurysms originate from one or both renal arteries. Suprarenal aneurysms affect the superior mesenteric and celiac arteries. Type IV thoracoabdominal aneurysms are suprarenal aneurysms that extend upward to the crux of the diaphragm.

BOX 66.2 Risk Factors for the Development of Abdominal Aortic Aneurysms

- Smoking
- Male gender
- Age
- Family history—especially male first-degree relatives
- Hypertension
- Dyslipidemia

Higher AAA expansion rate than do COPD patients not taking steroids.1 Hence, steroid use and coexisting disease are more likely to be responsible for the high prevalence of AAAs in patients with COPD.1 Finally, from a genetic standpoint, several screening studies suggest that male first-degree relatives of people with COPD are most at risk. Female first-degree relatives appear to be at similar risk, but the data are less certain.1 Familial aneurysms differ from nonfamilial aneurysms mainly in that they may develop at an earlier age.1 Existing genetic polymorphisms probably account for the familial clustering of AAAs, but this clustering could also result from exposure to common environmental factors, such as tobacco smoke.1

Histologically, AAAs develop as a result of a complex interplay of immunologically mediated proteases and antiproteases that cause destruction of elastin and collagen in the arterial wall. Recent research has focused on the role of matrix metalloproteinases (MMPs) in the degradation of elastin and collagen. The main proteins involved in AAA growth and rupture, respectively. In early aneurysm formation, elastic fibers are lost, fragmented, or attenuated, which contributes to development of the actual wall of the aneurysm.1,8 Once the concentration of medial elastin is severely decreased, the collagen-rich adventitial tissue constitutes the artery’s last mode of resistance, and once completely degraded, rupture inevitably ensues.1,8 The natural history of all arterial aneurysms encompasses gradual or sporadic growth in their diameter (or both) and accretion of mural thrombus.1 These features contribute to rupture, thromboembolic ischemic events, and compression or erosion of adjacent structures, three of the most common complications of AAAs.3

**PRESENTING SIGNS AND SYMPTOMS**

AAA continues to be such a difficult diagnosis because of vague and variable symptoms (Table 66.1), which carry large differential diagnoses. Vague symptoms such as back or abdominal pain often herald this diagnosis in its early (virtually asymptomatic) and potentially curative stages. The symptoms may masquerade as those of renal colic, diverticulitis, or gastrointestinal hemorrhage, thereby leading to a fatal misdiagnosis.3 Commonly, patients with nonruptured AAAs are seen only after suffering complications such as various thromboembolic events or after thorough evaluation for chronic vague abdominal and back pain.3

Nonruptured aneurysms are sometimes found incidentally. An astute clinician can find them on physical examination. Palpation of AAAs is safe and has not been reported to precipitate rupture.1 Abdominal palpation is moderately sensitive for the detection of AAAs that meet the size criteria necessary for surgical intervention, but even large aneurysms may be difficult to palpate, especially in obese patients. However, in the case of AAAs that are small or have already ruptured, physical examination alone is not nearly precise enough.3

When aneurysms rupture, the extent of shock varies according to the location and size of the rupture and the amount of delay before the patient is examined.3 AAAs that rupture...
antrolaterally dramatically violate the peritoneal cavity and are most often associated with sudden death. Patients with ruptured AAAs who reach a physician tend to have ruptures involving the posterolateral wall in the retroperitoneal space. A few of these patients with contained ruptures may even exhibit flank ecchymosis, a physical finding known as the Grey Turner sign.3 However, AAAs are not contained for long, and even these patients suffer the deleterious effects of a larger rupture if they fail to seek medical attention early or if the physician fails to recognize the signs of impending rupture.1

Differential Diagnosis and Medical Decision Making

As a result of the variable manifestations of AAAs just mentioned, the differential diagnosis is broad. Table 66.2 lists the differential diagnostic entities for AAA, along with priority actions for each. The correct diagnosis of AAA, regardless of whether it is ruptured, hinges on maintaining a high level of suspicion and pursuing an appropriate work-up.

Before the 1970s, standard plain radiographs were the only means by which to monitor the expansion rate of aneurysms. However, plain films are useful for this purpose only when the aneurysm has mural calcifications, which can be easily seen on radiographs. Additionally, the film may show obscuration of the psoas margin by a soft tissue mass and, possibly, extension of mural calcification into a periaortic soft tissue mass, thus hinting at a possible ruptured aneurysm.3 It is not the current standard of care to use plain radiographs for surveillance of AAAs, but quite a few such lesions are initially discovered as incidental findings on plain abdominal films obtained for other purposes.3

Ultrasoundography is an excellent choice for diagnosing AAAs for several reasons (Fig. 66.1, A). First, it is an easy, inexpensive, and accurate diagnostic modality that can evaluate the aorta in the transverse, longitudinal, and anteroposterior dimensions. For these reasons, it is ideal for initial evaluation, surveillance, and population screening with a sensitivity ranging from 92% to 99% and a diagnostic specificity of nearly 100%.3 In addition, ultrasonography provides the

emergency physician with a rapid, accurate mode of bedside assessment of a hypotensive patient with a suspected AAA who is too unstable to leave the emergency department (ED) for computed tomography (CT), magnetic resonance imaging (MRI), or magnetic resonance angiography (MRA). However, ultrasonography does have its limitations. Despite its efficacy in ascertaining the size of infrarenal aortic aneurysms, it is unreliable for imaging pararenal, juxtarenal, and suprarenal aneurysms and for imaging the common and internal iliac arteries for aneurysms. Spiral CT scans of the abdomen and pelvis with three-dimensional reconstruction are far superior to ultrasonography for this purpose and are most physicians’ first choice for diagnostic purposes (Fig. 66.1, B). Before the advent of CT, transcatheter arteriography was the “gold standard” for the preoperative assessment of AAAs despite its inability to determine the exact size of an aneurysm in the presence of a mural thrombus. CT has several advantages over this technique; it is cheaper, less invasive, carries a lower radiation dose, and provides information about the aorta and surrounding structures simultaneously. MRI and MRA can provide the same information as CT and can do so without the use of nephrotoxic agents. MRI and MRA are viable, albeit more costly and time-consuming options for patients with contraindications to iodinated contrast dye who are stable enough to leave the ED for an extended period.

Serial CT scans can be used preoperatively to give the vascular team charged with repairing the AAA several pieces of important information, especially if endovascular repair is being considered. CT can adequately visualize the proximal neck (the transition between the normal and aneurysmal aorta) and map out any dangerous venous anomalies that would make access difficult. CT can also measure the thickness of a mural thrombus and display the presence of blood within a thrombus. Blood within the thrombus is known as the crescent sign and has been highly touted by some as a reliable sign of impending rupture. Another important marker of aneurysm rupture is extravasation of contrast material. Finally, CT can demonstrate a contained rupture by showing clear evidence of draping of the posterior aspect of the aorta over the adjacent vertebral body; sometimes concomitant vertebral body erosion may be seen (Fig. 66.2).

At baseline, women have slightly smaller normal aortic diameters than men do (1.9 versus 2.3 cm); however, this difference in normal aortic diameter between the sexes is not substantial enough to warrant changing the upper limit of 3 cm that is used to characterize a small abdominal aortic aneurysm (AAA).

Patients who undergo emergency surgery for AAAs and are found to have intact, symptomatic aneurysms still have a mortality of 20% to 25% versus 5% for those undergoing elective repair.

In stable patients with abdominal or back pain in whom AAA is high on the differential diagnosis, the emergency physician should choose the type of computed tomography (CT) scan that allows diagnosis of the most likely cause; rapid abdominal CT without oral contrast enhancement may be most beneficial.
Currently, many researchers are actively investigating markers of rupture other than size. Much research revolves around the use of MMPs. These zinc- and calcium-dependent enzymes are produced by smooth muscle and inflammatory cells, and several of these proteinases may participate in AAA formation. McMillan and Pearce found that the amount of circulating MMP-9 is significantly higher in patients with AAAs. Lindholt et al. then noted an impressive association with the size and expansion rate of these aneurysms, which prompted many to theorize that serum levels of MMP may soon become a standard part of physicians’ diagnostic arsenal.

An approach to the diagnosis and management of AAAs is shown in Figure 66.3.

### TREATMENT

Any patient in whom a ruptured AAA or a symptomatic intact AAA is diagnosed needs emergency surgical intervention. Volume resuscitation and cross-matching of large amounts of blood should be undertaken immediately (see Fig. 66.3). Vascular surgery consultation should be sought as soon as the diagnosis is made.

The single most compelling reason to repair AAAs is to prevent fatal rupture. Besides rupture, other rare complications also mandate emergency repair, such as distal embolization and fistulous connections between the aorta and adjacent organs.

**Vital signs, intravenous access via 2 large-bore catheters, oxygen, complete blood count, serum chemistry panel, liver function panel, type and cross-match for 6 units of blood, urinalysis, prothrombin/partial thromboplastin time, electrocardiogram, portable chest radiograph**

**Unstable: low BP, tachycardia, ill-appearing**
- NS fluid boluses and un–cross-matched PRBCs; caution for too aggressive fluid resuscitation that may prevent local clot formation; be wary of potential of dilutional coagulopathy; aim for SBP 90-100 mm Hg; keep patient warm and consider level one infuser
- Spiral CT (fastest and easiest); MRI, angiography

**Stable, but concern for AAA**
- Aorta well visualized and no sign of aneurysm
- Stable and no clear aneurysm or doubt as to diagnosis
- AAA
- Surgery consultation
- Surgery consultation for operative repair
- Consider spiral CT

**Bedside US**
- Consider alternative diagnosis (see Table 66.2):
  - Musculoskeletal back pain, diverticulitis, cholecystitis, appendicitis, renal colic, pancreatitis, intestinal ischemia, bowel obstruction, myocardial infarction
  - Epididymal abscess or vertebral osteomyelitis, aortic dissection, cauda equina

structures.24 Once an AAA is identified, the obvious next step is to identify its size via ultrasonography, CT, MRI, or MRA to discern whether immediate intervention or periodic surveillance is warranted. One prospective but nonrandomized study demonstrated that observation alone is safe until an aneurysm undergoes a growth spurt or attains a threshold diameter of 5.0 cm.2,12 Aneurysms with a diameter of this size or larger weaken the aortic wall, which is then at higher risk for rupture.3 Estimates place the risk for rupture at 1% to 3% per year for AAAs measuring up to 5 cm, 11% per year for 5- to 7-cm aneurysms, and nearly 20% per year for aneurysms larger than 7 cm.9 Several studies have confirmed the linear association between AAA diameter and annual expansion rate. An observed rate of growth that surpasses these estimates is indicative of a “growth spurt” that may necessitate early elective aneurysm repair. Katzen et al.4 defined this “growth spurt” as an increase of 1 cm/yr. In addition, if the patient is a woman with smaller native vessels, one must remember that the relative size representing aneurysmal disease may be less than the conventional range of 5 to 5.5 cm.3

Prospective randomized trials comparing early intervention with expectant observation for infrarenal AAAs measuring 4.0 to 5.4 cm in diameter were conducted in the United Kingdom and by the U.S. Department of Veterans Affairs during the past decade.13,14 Elective surgical treatment was delayed in patients in the nonoperative cohort in each trial until their aneurysms exceeded 5.4 cm on serial imaging studies.3 On the basis of data regarding gender differences in the United Kingdom trial, a guidelines subcommittee of the American Association for Vascular Surgery and the Society for Vascular Surgery now recommends a diameter of 4.5 to 5.0 cm as the appropriate threshold for elective repair of asymptomatic infrarenal aortic aneurysms in women.3,15 The general consensus regarding suprarenal, pararenal, or type IV thoracoabdominal aortic aneurysms is that because of the higher risk for surgical complications with these aneurysms, elective intervention should be considered at a slightly larger diameter than with infrarenal aortic aneurysms.3

A caveat in successful watchful waiting is patient cooperation. Valentine et al.19 studied 101 patients with aneurysms less than 5.0 cm in diameter and did not find ruptures in patients who adhered to their follow-up program but did find a 10% rupture rate in patients who complied poorly. If continued surveillance is planned, lifestyle and dietary modification should be encouraged. As mentioned earlier, patients who smoke should be strongly encouraged to stop smoking and use any and all available smoking cessation aids, and they should undergo rigorous monitoring and treatment of blood pressure and cholesterol levels, as currently recommended for patients with atherosclerosis.1

Once an aneurysm has met the criteria for repair, the vascular surgeon can choose between open and endovascular repair when determining the operative approach. The most important factor determining the utility of either approach is patient selection. Generally, open surgical repair is appropriate for younger, low-risk patients, whereas endovascular repair is preferred for older, higher-risk patients3 (Box 66.3). Studies have shown lower 30-day mortality for endovascular repair (roughly 1.2%) than for open surgery (4.6%).4 Further study is required to determine whether either affords a long-term survival advantage. It is quite clear that both approaches decrease the risk for death from AAA rupture.4

Elective repair has resulted in a drastic reduction in mortality in comparison with emergency intervention because patients undergoing elective AAA repair are not suffering the catastrophic physiologic demands of sudden, rapid, high-volume loss at the time of repair. Additionally, they have had time to undergo a thorough preoperative evaluation. A number of studies have demonstrated that the mortality rate for open aortic aneurysm repair can be reduced to less than 2% in settings in which approximately 5% to 15% of patients undergo preliminary coronary artery intervention.17 Numerous studies have also been performed to elicit risk stratification methods to help the surgeon identify markers that herald higher morbidity and mortality risks in patients requiring intervention. Multiple studies have shown that the mortality rate with elective operations is so much lower than that with ruptured aneurysms that octogenarians should be offered surgical repair. Generally, AAA repair should be offered regardless of age.3,19,20

**BOX 66.3 Five Preoperative Risk Factors That Predict Mortality**

**Risk Factors**
- Age older than 76 years
- Serum creatinine value higher than 190 µmol/L
- Hemoglobin value below 9 g/dL
- Loss of consciousness
- Electrocardiographic evidence of ischemia

**Mortality**
- Mortality rate of 100% with 3 or more risk factors
- Mortality decreases to 48% with 2 risk factors
- Mortality decreases to 28% with 1 risk factor
- Mortality decreases to 18% in patients without risk factors
Study results do not agree regarding the extent to which race influences outcome. Some suggest that race plays no role, whereas others suggest that the mortality rate with elective AAA repair is higher in African Americans. Surprisingly, gender has proved to be influential. According to larger, population-based data sets in various states and countries, the mortality rate with both elective and ruptured aneurysm repair may be as much as 50% higher in women than in men.

With regard to emergency repair of ruptured AAAs, mortality depends on the hemodynamic status of patients at the time of surgery. In contrast to the decreased mortality associated with elective repair, no improvement in the mortality of patients with operatively managed ruptured aneurysms has been reported during the past decades, and it remains 30% to 70%. Clinical variables that have been found to significantly influence the mortality rate after ruptured aneurysm repair are presented in Box 66.4.

FUTURE THERAPY
Given the delineation of the role that MMPs play in aneurysm development and rupture, a fair amount of research has been undertaken in an effort to find inhibitors of these proteases and the utility of such agents in the treatment of small asymptomatic AAAs. Tetracyclines are potentially effective treatment for this purpose. Protracted administration of doxycycline has been associated with reduced plasma MMP-9 levels, but the long-term effects of this medication on the rate of aneurysm growth have yet to be determined. Interestingly, 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors have been found to decrease the expression of MMP in addition to their effects on cholesterol. Perhaps in time, statins will prove to be useful adjuncts to the prevention and treatment of AAAs. Finally, nonsteroidal antiinflammatory drugs and beta-blockers are being studied as possible medical treatments to prohibit the development of AAAs or inhibit their expansion rate.

Box 66.4 Variables That Significantly Increase the Mortality Rate in Patients After Repair of Ruptured Abdominal Aortic Aneurysms

- Low initial hematocrit
- Hypotension that requires resuscitation
- Cardiac arrest
- High Acute Physiological and Chronic Health Evaluation (APACHE) score
- Advanced age

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

ADMISSION AND DISCHARGE
Any patient in whom a ruptured AAA or a symptomatic intact AAA is diagnosed needs emergency surgical intervention. Treatment will continue in the surgical intensive care unit if the patient survives the operative repair.

The disposition of asymptomatic patients in whom the diagnosis is made incidentally depends on the size of the aneurysm, and such patients should be referred for possible elective repair or screening. An asymptomatic patient with an aneurysm larger than 5.5 cm should be referred to a surgeon immediately and should undergo preoperative testing.

COMPLICATIONS
As mentioned, AAAs are the thirteenth leading cause of death in the United States. Consequently, they are also associated with several other complications. First, as many as 13% of patients with aortic aneurysms have multiple aneurysms elsewhere, with some studies finding that more than 20% of patients with thoracic aortic aneurysms have concomitant AAAs. Thus, a patient in whom an aneurysm is discovered at any level should undergo a thorough examination of the entire aorta. A less common complication is aortocaval fistula. The overall prevalence of aortocaval fistula is 3% to 6% of all ruptured aortic aneurysms. The clinical features of patients with an acute aortocaval fistula usually consist of lower extremity swelling, engorged veins, and high-output cardiac failure. In fact, the development of high-output congestive heart failure with the perception of continuous abdominal noise is pathognomonic of an aortocaval fistula.

Other, even more rare complications of AAA can develop. One is rupture into the bowel, usually involving the duodenum. Exsanguination is the fatal result, but slow leaks may be manifested as melena and masquerade as peptic ulcer disease. The incidence of this complication is very low, and it is found less than 0.1% of the time at autopsy. However, the incidence rate of aortoduodenal fistula following previous repair is 0.5% to 2.3%. Exceptionally large or inflammatory aortic aneurysms can occasionally be associated with early satiety or gastric outlet symptoms because of duodenal compression. Finally, infectious or mycotic aneurysms are worthy of mention. Such an aneurysm may arise by one of two means. It may occur secondary to infection of a preexisting aneurysm, or the aortic wall itself may become infected and give rise to the development of an aneurysm, usually saccular in nature. Primary aortic infections are most commonly caused by Staphylococcus and Salmonella. Tuberculosis has also been found to be responsible for infection of aortic pseudoaneurysms.

PATIENT EDUCATION
Lifestyle modification is essential in the treatment of AAAs, as well as in limiting their progression; patients must be instructed to stop smoking and must be given help to do so. Many patients can avoid the complications of AAA rupture by developing long-lasting relationships with a primary care provider and adhering to their prescribed surveillance programs. Diameter is the best predictor of AAA rupture, and the follow-up interval depends on size. The risk for rupture of
AAAs according to diameter is as follows: less than 4 cm, 0% per year; 4.0 to 5.5 cm, 0.6% to 1% per year; 5.5 to 5.9 cm, 4.4% per year; 6.0 to 6.9 cm, 10.2% per year; and 7 cm or greater, 32.5% per year. In patients with an AAA, the aorta is believed to increase 0.5 cm in diameter every year, and these patients will eventually need surgery. As a result, the recommended screening intervals for patients with smaller baseline AAA diameters are as follows: less than 3.5 cm, 36 months; 4.0 cm, 24 months; 4.5 cm, 12 months; and 5 cm, 3 months. Patients should be educated about the early clinical signs of the rare but deadly complications of aortocaval and aortoenteric fistulas so that they can seek immediate medical attention. If discharged after an incidentally found aneurysm, close follow-up should be arranged as detailed earlier, and the patient should be cautioned to return if abdominal, back, or flank pain occurs.

Aortic Ultrasound
Vanessa Maria Piazza, Christine Butts, and Justin Cook

SUPPORTING EVIDENCE
A large amount of research has confirmed bedside ultrasound to be a useful and lifesaving tool in the emergency department (ED). Tayal et al. conducted a prospective study of the accuracy and outcome of bedside ultrasound for the diagnosis of AAA by emergency physicians. They evaluated 125 patients suspected of having an AAA with bedside ultrasound. Twenty-nine patients were found to be positive for AAA, for a positive predictive value of 93% and a negative predictive value of 100%. The sensitivity was 100% with a specificity of 98% for 10 of the 27 patients found to have an AAA, and disposition was immediate to the operating room without a confirmatory study.3,7

Another emergency medicine study performed in 2005 evaluated 238 patients who arrived at the ED with symptoms suggestive of a ruptured AAA. Third-year emergency medical residents, trained according to guidelines from the American College of Emergency Physicians, performed all ultrasound examinations. Thirty-six aortic abnormalities were diagnosed with a sensitivity of 100% and specificity of 100% for this end point in comparison with “gold standard” diagnostic testing.8

Knaut et al. assessed the accuracy of measurements taken by emergency physicians via ultrasound versus measurements taken by CT. They found that in all cases, their measurements approximated those found on CT within 1.41 cm or less.9

Plummer et al. randomized patients to ultrasound versus standard-of-care diagnostics and compared time to diagnosis and to the operating room. Ultrasound improved time to diagnosis (5.4 versus 83 minutes) and improved time to disposition for patients requiring operative intervention (90 versus 12 minutes).4

SCANNING PROTOCOLS
Bedside ultrasound of the aorta can be completed in 2 to 3 minutes. To rule out the presence of an aneurysm, the entire length of the abdominal aorta from the diaphragmatic hiatus to the aortic bifurcation should be evaluated in both the longitudinal and transverse planes. A low-frequency transducer should be selected for this examination. A 2- to 5-MHz curvilinear transducer will be the best choice for most patients because it offers adequate depth and resolution. A phased-array or microconvex transducer can also be used.
The examination begins just below the patient’s xiphoid process. With the indicator pointing toward the patient’s right, the transducer should be facing straight down to the patient’s back (Fig. 67.1). Although the aorta may be identified immediately, some effort is frequently required to orient the sonographer to the anatomy. The easiest landmark to identify initially is the vertebral body. It is seen as a hyperechoic (white) arc casting a dark acoustic shadow, usually near the bottom of the screen. Just above the vertebral body, two circular, anechoic (black) vessels should be seen (Fig. 67.2). The aorta lies to the patient’s left and the inferior vena cava (IVC) lies to the patient’s right. The IVC is oval shaped and compressible and has thinner walls. The aorta is round, noncompressible, thicker walled, and pulsatile. A measurement should be taken in this transverse orientation, from outer wall to outer wall in both the anterior-posterior and side-to-side planes (Fig. 67.3). While maintaining contact with the skin, the transducer should be moved caudally to follow the course of the aorta. From this point, the branches of the aorta can be seen, and the first branch is the celiac trunk. Caudally, the superior mesenteric artery may also be seen, followed by the bifurcation of the celiac trunk, which is often referred to as the “seagull sign” (Fig. 67.4). As the examination proceeds caudally, a second measurement should be taken midway between the xiphoid process and the umbilicus. Theoretically, this should be near the origin of the renal arteries. The measurement should be taken in the transverse orientation, from outer wall to outer wall and in both the anterior-posterior and side-to-side planes.

The examination continues caudally until the aorta is seen to bifurcate into the common iliac arteries just above the xiphoid process. Once this bifurcation is identified, a third measurement should be taken just above this location in the same manner described previously. The examination concludes with evaluation of the aorta in the longitudinal, or sagittal, plane. Beginning again just caudal to the xiphoid process, the transducer is now placed with the indicator
Frequently, mural thrombus is seen within the lumen of an AAA as a result of decreased blood flow at the periphery of the vessel (Figs. 67.7 and 67.8). Thrombus is seen as a hypoechoic (dark gray) crescent along the wall of the aneurysm. The type of aneurysm may also be apparent by examining the aorta in multiple dimensions. A fusiform aneurysm will be dilated in a uniform manner around the circumference of the vessel, whereas a saccular aneurysm is a focal dilation of one aspect of the vessel. If an aneurysm is found, the peritoneum should be evaluated for the presence of free fluid with a FAST examination (Fig. 67.9).

**Fig. 67.5** Normal anatomy of the aorta in a longitudinal or sagittal orientation. The celiac trunk can again be seen as the first branch, with the superior mesenteric artery just beyond it.

**Fig. 67.6** Transverse image of an abdominal aortic aneurysm. Note the measurements of 3.35 × 3.85 cm. The inferior vena cava is seen to the patient’s right of the aorta, and the vertebral body is seen below the two vessels. Note also that there appears to be an echogenic flap within the aorta, possibly representing an aortic dissection.

Directed toward the patient’s head. It is frequently necessary to move the transducer slightly toward the patient’s left side to visualize the aorta (Fig. 67.5). The aorta is distinguished from the IVC as described previously. This longitudinal view of the aorta allows additional information and frequently details suspected abnormalities. Measurements of the diameter of the aorta should not be done in this plane. Underestimation of the diameter may occur if the beam is off center, known as the “cylinder” artifact.

**ABNORMAL FINDINGS**

An AAA is defined as an aortic diameter greater than 3 cm or greater than 50% of normal. This diagnosis can easily be made with simple measurements of aortic diameter (Fig. 67.6). Frequently, mural thrombus is seen within the lumen of an AAA as a result of decreased blood flow at the periphery of the vessel (Figs. 67.7 and 67.8).
earlier, this is a rare location for rupture. Rupture of an AAA should be assumed in any patient with an aneurysm and evidence of acute decompensation (e.g., hypotension). The abdominal aorta must be seen in its entire length to rule out an AAA. Aneurysms are frequently focal and confined to a relatively small portion of the vessel, so evaluation of only portions of the aorta may result in overlooking a significant aneurysm.

**PITFALLS**

Frequently, a beginning sonographer has difficulty identifying and following the abdominal aorta. Patient habitus and the presence of bowel gas may result in a large amount of hazy gray scatter artifact. To initially identify the aorta, a helpful first step is increasing the overall depth of the image. Some patients may require a depth of 30 cm to “see” far enough into the abdomen. The vertebral body makes a helpful landmark because it typically stands out among the other structures in the abdomen. Careful evaluation of the image for pulsations or use of the color flow box may help in initially identifying the aorta (Fig. 67.10).

Once the aorta has been identified, another common pitfall is an inability to follow the aortic course to its bifurcation because of bowel gas and body habitus. To overcome this challenge, application of steady pressure from the subxiphoid area to the umbilicus will frequently cause bowel gas to disperse enough to allow a sufficient image. Additionally, the patient can be placed in either the right or left decubitus position to help displace abdominal gas.

Once technical difficulties have been overcome, the sonographer should be mindful to avoid diagnostic errors. Bedside ultrasound seeks to identify the presence of an aneurysm and is most sensitive when used for this purpose. Because the aorta is a retroperitoneal organ, it most often ruptures into this space, thus making diagnosis difficult. Although free fluid may be seen within the peritoneum as described earlier, this is a rare location for rupture. Rupture of an AAA should be assumed in any patient with an aneurysm and evidence of acute decompensation (e.g., hypotension). The abdominal aorta must be seen in its entire length to rule out an AAA. Aneurysms are frequently focal and confined to a relatively small portion of the vessel, so evaluation of only portions of the aorta may result in overlooking a significant aneurysm.

Peripheral Arterial Disease

Christopher Ross and Theresa Schwab

**KEY POINTS**

- Intermittent claudication is the earliest clinical manifestation of pathologically significant peripheral arterial disease.
- The ankle-brachial index can help confirm clinical suspicion of occlusive arterial disease.
- Ischemic rest pain signals critical, limb-threatening disease.
- The classic manifestation of acute arterial occlusion is described by the six “P’s”: pain, paresthesia, pallor, and pulselessness.
- Treatment of nonischemic peripheral arterial disease consists of modification of risk factors, exercise programs, and medications aimed at platelet inhibition.
- Prompt initiation of therapy is the most important aspect of the treatment of acute limb ischemia, and patients should receive a heparin bolus followed by an infusion, ideally even before diagnostic testing is begun.
- Treatment of ischemic peripheral arterial disease depends on whether the extremity is viable (angiography to assess the extent of disease), nonviable (primary amputation), or threatened (immediate surgical intervention required).

**EPIDEMIOLOGY**

The most common term used to describe atherosclerotic vascular disease of the lower extremities is peripheral arterial disease (PAD). In North America and Europe, it is estimated that 27 million individuals are affected by PAD. In a significant proportion of patients the disease is occult but is nevertheless an important indicator of significant cardiovascular events. Systemic atherosclerotic disease with damage to end-organs other than the heart continues to be associated with high morbidity and mortality, and surprisingly little research is being done on it.

By 50 years of age the prevalence of PAD is 2% to 3%, and it rises to 20% in those older than 75 years. The clinical findings of PAD in patients older than 50 years is as follows: 10% to 35% have classic claudication, 20% to 50% are asymptomatic, 40% to 50% have atypical leg pain, and the remaining 1% to 2% have critical ischemia. Women have a relative risk of 0.7 in comparison with men. African American subjects have the highest risk for PAD (2.5) relative to the white population, followed by Hispanic subjects (1.5).

Box 68.1 lists the risk factors for PAD. They are similar to the risk factors that promote the development of coronary atherosclerosis. The risk factor with the highest correlation to PAD is cigarette smoking. When compared with nonsmokers, smokers have a 1.7- to 5.6-fold increase in the development and progression of atherosclerosis in the peripheral vasculature. In patients with symptomatic PAD, smoking increases this risk 8 to 10 times. Risk increases in a powerful dose-dependent manner according to the number of cigarettes smoked per day and the number of years of smoking. Diabetes increases the risk for PAD, 3.5 times in men and 8.6 times in women. Diabetic patients are also 7 to 15 times more likely to require amputation. The Framingham Heart Study found that risk for the development of intermittent claudication was 2.5-fold and 4-fold higher in men and women, respectively, who had hypertension and that this risk was proportional to the severity of the hypertension. Genetic predisposition represents an important risk factor for atherosclerosis, and such predisposition accounts for as much as 50% of the risk in some studies. Patients who have PAD also have a high incidence of coronary heart disease (CHD), and in general, patients have a two to four times higher incidence of CHD and cerebrovascular disease if PAD is also present.

**PATHOPHYSIOLOGY**

Atherosclerosis was originally thought to be primarily lipoprotein accumulation but is now better understood, fundamentally, as chronic inflammatory disease of the arterial system. The inflammatory process leads to plaque disruption and thrombosis, and the plaques that are vulnerable are characterized by a large lipid core, a thin fibrous cap, and inflammatory cells at the thinnest portion of the cap surface (Fig. 68.1). Plaque rupture has been shown to be critical in the development of acute coronary syndromes, but the importance of this event in patients with PAD is not known at this time.
**BOX 68.1 Risk Factors for Lower Extremity Peripheral Arterial Disease**

Age 70 years and older
Age younger than 50 years with diabetes and one other atherosclerotic risk factor (smoking, dyslipidemia, hypertension, or hyperhomocysteinemia)
Leg symptoms with exertion (suggestive of claudication) or ischemic rest pain
Abnormal lower extremity pulse findings
Known atherosclerotic coronary, carotid, or renal artery disease

---

The vascular smooth muscle cell is important in the development of atherosclerosis. Once activated, the cell migrates into the intima and begins to proliferate and secrete matrix proteins and enzymes. This step has been shown to be important in the development of stenosis both in the atherosclerotic vessel and in vessels that have been stented. In addition, the vessel often constricts rather than dilates, thereby narrowing the lumen even more. Progression of PAD can result from worsening local atherosclerotic disease or a superimposed embolic, thrombotic, inflammatory, traumatic, or vasospastic event.

**THROMBOEMBOLISM**

More than 80% of arterial emboli originate in the heart and travel to the extremities, the lower extremities being much more frequently affected than the upper ones. Emboli typically lodge in places with acute narrowing of the artery, such as an atherosclerotic plaque or a point where the vessel branches. The frequencies with which emboli lodge in various areas are as follows: femoral arteries, 28%; arm vessels, 20%; aortoiliac vessels, 18%; popliteal arteries, 17%; and visceral vessels, 9%.

Because of the size of most emboli, the femoral and popliteal arteries are involved more often than the larger aortic and iliac vessels. Atrial fibrillation can lead to thrombosis of the left atrium and is present in 60% to 75% of patients with embolic events. Valvular heart disease (aortic and mitral) accounts for approximately 5% to 10% of cases of thromboembolic disease. The amount of tissue destruction depends on the size of the vessel, the extent of obstruction, and the amount of collateral circulation available to compensate. Once the embolus has lodged in the vessel wall, further propagation can occur either distally or proximally via thrombosis, which can further exacerbate the ischemia.

**ATHEROEMBOLISM**

Debris from atherosclerotic plaque can break off in proximal vessels and give rise to atheroemboli. Atheroemboli are less likely to produce symptoms of acute arterial occlusion. The atheroembolus is usually irregularly shaped and nondistentensible, thus leading to incomplete occlusion with secondary ischemic atrophy. One exception is blue toe syndrome, in which atheroemboli cause complete occlusion of the digital arteries in the foot. In patients with simultaneous evidence of both venous and arterial embolism, a patent foramen ovale should be considered.

**INFLAMMATION**

Irradiation, drugs, trauma, or bacterial or fungal invasion can result in an inflammatory arterial injury. Infectious causes lead to direct invasion of the vessel wall and are usually related to intravenous drug abuse, infective endocarditis, or generalized sepsis.

**TRAUMA**

Blunt injury to vessel walls can result in disruption of the intima, which can then cause obstruction and thrombosis. Usually, it takes hours to days for complete occlusion to become manifest. Arterial lacerations can be partial or complete, and either type can cause distal ischemia and infarction. Partial arterial lacerations continue to bleed because of the intact portion of the vessel, and such bleeding can result in hematoma formation outside the vessel and thrombosis within the vessel. The hematoma can cause progressive pain, deformity, nerve compression, and subsequent vascular compromise. Complete arterial lacerations actually bleed very little acutely because of spasm of the transected ends. Eventually,
however, the spasm relaxes, which can lead to delayed bleeding, and the thrombus on the distal side may separate and move distally.

**VASOSPASM**
Abnormal vasomotor responses in distal small arteries can cause ischemic symptoms without tissue loss.

**ARTERIOVENOUS FISTULAS**
Sometimes there may be communication between the arterial and venous systems, which can cause vascular distention, tortuosity, aneurysm formation, and alterations in hemodynamics that are favorable for the development of thrombosis. The fistulas result in elevation of the local venous system, which can lead to skin breakdown in the form of dermatitis and ulceration.

**PRESENTING SIGNS AND SYMPTOMS**
The clinical signs and symptoms of PAD may be nonspecific and be manifested in a variable fashion according to degree and location of the atherosclerotic disease, as well as the presence of other previously described pathologic processes, such as thromboemboli, atheroemboli, inflammation, trauma, and vasospasm. The clinical spectrum ranges from a nonspecific systemic illness to a catastrophic event such as an ischemic leg. The gastrointestinal tract is an often-overlooked area of involvement that has been shown to be involved in about a third of cases.16 Livedo reticularis is a red-blue netlike finding in patients with PAD and appear in approximately a third of cases. Skin manifestations are not only common in patients with PAD and appear in approximately a third of cases.16 Livedo reticularis is a red-blue netlike motting of the skin and represents embolization to the skin. Such motting is generally seen on the legs, buttocks, and thighs and rarely involves the arms.

Key components of the vascular review of symptoms and family history are listed in Box 68.2. Physical findings in patients with PAD are listed in Box 68.3. Despite general relationships between PAD and the site of pain, the history and physical examination are not reliable for the detection of lower extremity PAD. Relying solely on the presence of classic claudication will miss up to 90% of cases. Physical examination can also be unreliable. For instance, an abnormal femoral pulse has high specificity and positive predictive value but low sensitivity for large-vessel disease. The best single discriminator is an abnormal posterior tibial pulse.17

**ACUTE ARTERIAL OCCLUSION**
Patients with acute arterial occlusion commonly complain of a sudden onset of pain and coldness distally, on the side of the occlusion (Fig. 68.2). As the ischemia progresses, the classic findings of acute arterial occlusion become evident, as described by the six “P”s: pain, polar (cold) sensation, paraesthesia, paralysis, pallor, and pulselessness. As the peripheral nerves become ischemic, paresthesias, numbness, and then paralysis develop sequentially. The sensory peripheral nerves are affected first, with decreases in proprioception and light touch, and then the larger pain and motor fibers become involved and give rise to a loss of sensation, weakness, and paralysis. Paralysis is usually a bad prognostic sign for reversibility of the ischemia. Signs of ischemia can be seen distal to the level of arterial occlusion. During the first 8 hours after the ischemic insult, the extremity looks pale because of the spastic nature of the arterial tree surrounding the region. Twelve to 24 hours after the injury, the extremity may become cyanotic and mottled. As arterial flow ceases, venous drainage also slows or stops, thereby leading to profound stasis, which further aggravates the damage. On careful examination, the cold part of the extremity can easily be demarcated from its

**BOX 68.2 Key Findings in the Vascular Review of Systems**
- Any exertional limitation of the lower extremity muscles or any history of walking impairment (fatigue, aching, numbness, or pain). The primary site or sites of discomfort in the buttock, thigh, calf, or foot should be recorded along with the relationship of such discomfort to rest or exertion
- Any poorly healing or nonhealing wounds on the legs or feet
- Any pain at rest localized to the lower part of the leg or foot and its association with the upright or recumbent positions
- Postprandial abdominal pain that is reproducibly provoked by eating and is associated with weight loss

**BOX 68.3 Key Components of the Vascular Physical Examination in a Patient with Possible Peripheral Arterial Disease**
- Measurement of blood pressure in both arms and notation of any interarm asymmetry
- Palpation of the carotid pulses and notation of carotid upstroke and amplitude and the presence of bruits
- Auscultation of the abdomen and flank for bruits
- Palpation of the abdomen and notation of the presence of aortic pulsation and the maximum diameter of the aorta
- Palpation of pulses at the brachial, radial, ulnar, femoral, popliteal, dorsalis pedis, and posterior tibial sites
- Auscultation of both femoral arteries for the presence of bruits
- Assessment of pulse intensity, which should be recorded numerically as follows: 0, absent; 1, diminished; 2, normal; 3, bounding
- Inspection of the feet for evaluation of color, temperature, and integrity of the skin and intertriginous areas and recording of the presence of ulceration
- Documentation of the presence of symmetry, edema, and venous distention of the lower extremities
- Recording of additional findings suggestive of severe peripheral arterial disease, including distal hair loss, trophic skin changes, and hypertrophic nails
Fig. 68.2 Large saddle clot at the bifurcation of the aorta at the iliac vessels. This clot not only can cause symptoms by itself but can also embolize more distally.

warmer proximal portion. The ischemia is unlikely to be reversible if the affected limb is paralyzed.

**INTERMITTENT CLAUDICATION**
The primary symptom of lower extremity atherosclerotic disease is intermittent claudication. Claudication, from the Latin word for “limp,” is defined as reproducible discomfort of a defined group of muscles that is induced by exercise and relieved with rest. It results from an imbalance in the blood flow needed to meet the metabolic demands of the tissue. Intermittent claudication has three major clinical features: it is consistent and reproducible from day to day, symptoms resolve within a couple of minutes after cessation of exercise, and discomfort occurs again at the same distance once the patient resumes the activity. The symptoms usually occur gradually and may be absent or minimal, even in those with significant disease. The pain may also be felt in the thigh, hip, and buttock as the level of obstruction moves proximally. If many of the vessels are involved, the most distal muscle group is affected first, followed by proximal migration as the patient continues to walk. The pain is primarily unilateral at onset but may be bilateral if distal aortic occlusion occurs. Progressive arterial insufficiency causes a collateral circulation to develop, which will allow the patient’s symptoms to not progress despite worsening of the culprit artery. As described, there is a relationship between the site of pain and the site of arterial disease, as follows: foot (tibial and peroneal artery), calf (superficial femoral artery or popliteal artery), thigh (common femoral artery or aorta and iliac artery), and buttocks and hips (aorta and iliac artery).

**REST PAIN**
Ischemic pain at rest can be a symptom of severe to critical limb ischemia. The pain typically occurs at night when the patient is supine, and the patient may awaken from sleep with pain in the toes or forefoot. The pain is generally worse in a single extremity and is relieved by dependency. The patient may either stand up or hang the legs over the edge of the bed for relief. In this scenario, physical examination may show marked pallor with elevation of the legs, marked rubor with dependency, and delayed venous filling times. Usually by the time that rest pain occurs, severe arterial insufficiency is present in multiple arterial segments.

After rest pain, progression of disease causes necrosis of tissue, generally between two toes. Eventually, the ulcers may coalesce or progress to dry gangrene over the tips of the toes or at pressure points. Peripheral gangrene arising from an arterial cause may be difficult to differentiate from that with a venous cause. A patient with arterial ischemia exhibits severe ischemic changes followed by edema because the limb is kept in a dependent position. With venous gangrene, however, the edema occurs first, before the onset of frank ischemic changes.

### Differential diagnosis and medical decision making
The clinician will often need to determine whether the patient’s symptoms are related to peripheral neuropathy or ischemic disease. Patients with neurologic disease usually have bilateral leg pain that is not relieved by dependency, as well as neurologic signs such as decreased deep tendon reflexes and loss of touch and vibratory sensation. With ischemia, the sensory peripheral nerves are affected first and result in decreases in proprioception and light touch; the larger pain and motor fibers then become involved, which leads to loss of sensation, weakness, and subsequently paralysis.

Once the clinician is convinced that the patient’s symptoms are related to PAD, the first priority is to determine whether the symptoms represent PAD without occlusion (nonischemic) or whether ischemic PAD is present. The next step is to determine whether the extremity is viable, threatened, or nonviable (Box 68.4). When arterial blood flow is insufficient to meet the metabolic demands of resting muscle or tissue,
limb-threatening ischemia results. This is the most common indication for emergency arterial reperfusion. The selected group of patients requires immediate assessment of their vascular system. Arteriography provides the most useful information in the setting of acute arterial occlusion because in addition to providing information on anatomy, it can distinguish between embolism and thrombosis. Embolism has a sharp cutoff of contrast agent with a reverse meniscus sign; thrombosis usually has a more tapered cutoff. Diffuse atherosclerotic disease is also usually found around a thrombotic occlusion.

**ACUTE ARTERIAL OCCLUSION**

Acute arterial occlusion (critical limb ischemia) is defined as a sudden decrease in limb perfusion that causes a potential threat to limb viability in patients seen within 2 weeks of the acute event. Acute arterial occlusion can be the result of emboli from a distant source, thrombosis of a previously patent artery, or direct trauma to an artery (Box 68.5).

**BLUE TOE SYNDROME**

Blue toe syndrome is a commonly seen condition characterized by the sudden appearance of a cool, painful, cyanotic toe or forefoot. It generally occurs in the presence of a palpable peripheral pedal pulse and warm forefoot. This syndrome is usually due to embolic occlusion of the digital arteries as a result of atheroemboli from proximal arterial sources. It is not typically due to local atherosclerotic disease. Identification of the embolic source and treatment of the diseased segment are required.

**ANKLE-BRACHIAL INDEX**

Because blood flow is diminished, the most common sensor used is the Doppler flowmeter. Calculation of the ankle-brachial index (ABI) is an accurate way to diagnose PAD. The ABI is a simple and relatively inexpensive test to confirm the clinical suspicion of occlusive arterial disease, and it provides a measure of the severity of the peripheral vascular disease. The ABI is calculated by measuring systolic blood pressure with a Doppler probe in the brachial, posterior tibial, and dorsalis pedis arteries. The highest of the measurements in the ankle and foot is divided by the highest in the upper extremity. The ABI in normal individuals is 1.0 or greater; values higher than 1.3 usually indicate a calcified vessel that is noncompressible. An ABI of less than 0.9 has 95% sensitivity (100% specificity) for PAD and is associated with 50% or greater stenosis in one or more major vessels (Box 68.6).

**IMAGING**

**Duplex Ultrasonography**

The term *duplex ultrasonography* refers to B-mode real-time imaging and pulsed Doppler analysis of the velocity of flowing blood in arteries and veins. Arterial duplex ultrasonography provides a “road map” of stenosis of the arteries of the lower extremities. The sensitivity of duplex ultrasonography in detecting occlusions and stenosis is 95%, with a specificity of 98%. The utility of performing duplex ultrasonography in the emergency department is limited because most decisions about patient care are based on the history and physical findings.

**Computed Tomographic Angiography**

Computed tomographic angiography (CTA) is a vascular imaging technique that can be used to assess many vascular diseases rapidly and safely. Multidetector computed tomography can provide very high-quality resolution in comparison with the single-detector scanners from the not-so-distant past. CTA has the following advantages over regular angiography: (1) the images can be reconstructed from multiple angles and in multiple planes, (2) soft tissues and other anatomic structures are better identified, and (3) the technique is less invasive with fewer complications and lower cost. CTA does, however, expose patients to radiation and potentially nephrotoxic dye loads. Because PAD is commonly multifocal, both arterial inflow and runoff should be imaged in their entirety. Studies have shown 100% concordance of CTA with angiography, as well as better visualization of other portions of distal vessels that are not seen with traditional angiography.

**Magnetic Resonance Angiography**

Magnetic resonance angiography (MRA) of the peripheral vasculature can be performed quickly and accurately. MRA has two distinct advantages over CTA: its contrast agents are not nephrotoxic, and images are obtained without exposure to radiation. The quality of MRA is now so good that it has virtually surpassed angiography for evaluating stable patients.
with PAD to determine what type of intervention is most appropriate. MRA can assess not only vessel occlusion and stenosis but also the arterial wall for evidence of atherosclerosis. MRA investigations require prolonged study times and transport from the emergency department, thus limiting their usefulness in emergency situations.

**Diagnostic Angiography**

Catheter-based angiography yields images of the vascular lumen. Any condition that requires luminal evaluation for diagnosis or characterization is best assessed with this technique. Catheter-based angiography is very important in the evaluation of atherosclerotic, thrombotic, and embolic occlusions because it provides access for some definitive modalities and is indispensable before most percutaneous and surgical procedures related to lower extremity atherosclerotic disease. The contrast materials used today are much safer and more tolerable than previous agents. One adverse effect of contrast administration, renal toxicity, has not been reduced by use of low-osmolality agents. Contrast agent–induced renal impairment can be decreased by identifying patients at risk for renal impairment, attempting to correct comorbid conditions, limiting the amount of contrast agent given, and ensuring appropriate hydration of the patient.

In digital subtraction angiography (DSA), the image is acquired, converted with an image intensifier, transferred to a monitor, and saved in digital format. DSA is a computer-assisted radiographic technique that subtracts images of bone and soft tissue to permit viewing of the cardiovascular system. Structures that do not change during injection are canceled out, which results in the “disappearance” of structures such as bone, soft tissues, and air. Improved hardware, software, and speed of the techniques combined with better outcomes from interventions mean that DSA is heavily relied on for vascular disease. The need for lower concentrations of iodinated contrast agents or the use of nonnephrotoxic agents also makes it a more desirable imaging technique than regular angiography. The major attributes of DSA that contribute to its importance are high resolution, ability to selectively evaluate individual vessels, and ability to access direct physiologic information from the tissues. Despite the diagnostic paradigm shift away from angiography, DSA is a cornerstone technology in PAD intervention and will probably remain so for the foreseeable future.

**TREATMENT**

The spectrum of PAD ranges from asymptomatic to critical limb ischemia, and coronary artery disease and other atherosclerotic vascular disorders may coexist with PAD. Indications for urgent intervention are (1) incapacitating claudication that interferes with work or lifestyle and (2) limb salvage in persons with limb-threatening ischemia, as manifested by rest pain, nonhealing ulcers, or infection or gangrene.

Prompt initiation of therapy is the most important aspect of the treatment of acute limb ischemia. Patients should immediately receive a heparin bolus followed by an infusion to prevent clot propagation and inhibit thrombosis distal to the lesion, where low flow or stasis is present. Heparin should be administered before diagnostic testing is performed. Subsequent therapy depends on whether the extremity is viable, threatened, or nonviable.

**Patients with Viable Extremities**

Patients found to have an ischemic but viable extremity on clinical examination should undergo urgent arteriography. Once the anatomy has been defined, vascular surgeons can determine whether surgical or intraarterial thrombolytic therapy is needed. One study reported limb salvage rates of approximately 70% with both thrombolytic therapy and surgical intervention in this patient population. The important thing for the emergency physician to remember is that thrombolytic therapy is limited by the length of time needed to dissolve the thrombus and the severity of the ischemia. Thrombolytics are given at the site of occlusion through the catheter used for angiography. This method has been shown to have a better outcome with fewer bleeding complications than is the case with intravenous administration. Both urokinase and tissue plasminogen activator have been studied and appear to be similar in outcome measures. Patients who have had ischemic symptoms for less than 14 days and are treated with thrombolytics have better amputation-free survival and shorter hospital stays than do those who undergo surgery; patients with ischemic symptoms for longer than 14 days have a better outcome with surgical intervention. In addition, in patients who have received thrombolytic therapy and eventually require surgical intervention, the magnitude of the surgical procedure is less than in patients who have not received thrombolytics.

The surgeon and interventional radiologist help determine the optimal therapy for a patient with limb ischemia and a viable extremity according to (1) the location and length of the lesion, (2) the cause (embolus versus thrombus), (3) the duration of symptoms, and (4) the suitability of the patient for surgery. In general, smaller, more distal emboli are best treated with thrombolytics, whereas a large embolus at a more proximal location is best treated by embolectomy (Figs. 68.3 and 68.4).

**Patients with Threatened Extremities**

Patients with threatened extremities should undergo immediate surgical revascularization. The vast majority of such patients have had an embolic event. Irreversible changes, including necrosis, may occur within 4 to 6 hours of the initial insult, thus leaving a fairly small therapeutic window. The small amount of time available makes thrombolytic therapy of limited utility (Figs. 68.5 and 68.6).

Surgery usually reveals an embolus that can be removed by embolectomy. After embolectomy, most surgeons perform intraoperative arteriography to assess distal blood flow. If small distal emboli are found after embolectomy, intraoperative thrombolytic therapy may be considered. If the ischemia has been prolonged, compartment syndrome may result once blood flow is restored. Therefore, oral anticoagulation should be instituted after the procedure to prevent subsequent embolization.

**Patients with Nonviable Extremities**

If clinical evaluation of a patient’s extremity reveals nonviability, amputation should proceed promptly. Angiography is not normally required to make this diagnosis, and the clinical findings dictate the level of amputation. In general, surgeons...
try to preserve as many joints as possible to decrease the work of ambulating with a prosthesis. If amputation is not performed in an expedient manner, the patient may have complications such as sepsis, acute renal failure, rhabdomyolysis, hyperkalemia, and cardiovascular collapse.

**NONISCHEMIC PERIPHERAL ARTERIAL DISEASE**

Patients who have nonischemic PAD should be referred for follow-up with vascular surgery. Initial therapy should include institution of an exercise program and risk factor modification, along with antiplatelet therapy.29

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Vascular diseases are common, and prompt treatment can diminish disability and death. Individual health can be preserved (better functional status and survival) and public health goals achieved (e.g., diminished rates of amputation, fewer cardiovascular ischemic events and death) by establishing an accurate vascular diagnostic assessment and treatment plan. Patients with nonischemic PAD can be discharged with instructions for risk factor modification and follow-up with a vascular surgeon. Any patient with signs of ischemic PAD should be admitted to the hospital as part of evaluation and treatment.

Of patients in whom PAD develops in association with symptoms of intermittent claudication, 70% to 80% will have stable symptoms at 5 years, with the remaining 10% to 20%
having worsening claudication. Five percent to 10% will require revascularization in the subsequent 5-year period. Over the same interval, about 1% to 2% of patients will have critical leg ischemia, some of whom will require amputation. Predictors of progression include cigarette smoking, diabetes, high cholesterol, and hyperlipidemia.

It should be noted that there is both wide geographic and wide ethnic variation in the outcome of PAD. White persons are more likely to undergo aortoiliac surgery and less likely to need lower extremity amputation than other ethnic groups are. This discrepancy cannot be explained by the higher prevalence of risk factors in other ethnic groups.

**RED FLAGS**

Risk for peripheral arterial disease increases in a powerful dose-dependent manner with the number of cigarettes smoked per day and the number of years of smoking. Ischemic fissures, decubitus ulcers of the ankles and heels, and ischemic ulcers correlate with arterial insufficiency. More than one third of patients with embolic disease have skin manifestations, thus making them the most common physical finding. In contrast to patients with ischemia pain, those with peripheral neuropathy usually have bilateral leg pain that is not relieved by dependency, as well as neurologic signs such as decreased deep tendon reflexes and loss of touch and vibratory sensation. Attempts at limb salvage in a patient with hard neurologic findings indicative of prolonged ischemia may endanger the life of the patient because of the severe metabolic changes that occur after revascularization. Acute extremity ischemia is associated with high rates of limb loss (30%) and hospital morbidity and mortality (20%).

**PATIENT TEACHING TIPS**

Physicians must educate patients on the importance of pain as a symptom of significant arterial disease and the need for immediate evaluation to save a limb. Modification of risk factors, especially smoking, can not only arrest progression of the disease but may also, in some cases, reverse some of the clinical effects. Patients with peripheral arterial disease must also undergo testing for associated coronary artery disease because of the close association of the two disease processes.

REFERENCES

studies have found that hypertensive emergencies account for 28% of all patient visits to the emergency department (ED) for medical complaints, 21% of which were hypertensive urgencies and 6.4% were hypertensive emergencies. Pre-eclampsia (pregnancy-induced hypertension with proteinuria) occurs in 7% of pregnancies and most frequently in primigravidas. Uninsured populations, who receive a disproportionate amount of their care in EDs, have a higher prevalence and poorer control of elevated blood pressure. In inner-city public EDs, as many as 20% of the adult population have been found to have blood pressure higher than 140/90 mm Hg. As an important cardiovascular, cerebrovascular, and renal failure modifiable risk factor, a modest 5–mm Hg decrease in the population is estimated to reduce stroke mortality by 9% and cardiovascular deaths by 12%.

PATHOPHYSIOLOGY
Hypertension is multifactorial and includes genetic and environmental causes, and the causes of hypertensive crises are poorly understood. Hypertension coincides with elevated peripheral vascular resistance (PVR) and normal to low cardiac output. The mechanism of the disease is probably an imbalance in autoregulation of the renin-angiotensin system. Malignant-accelerated hypertensive crises are thought to be due to an abrupt increase in PVR caused by humoral vasoconstrictors leading to endothelial injury, vascular permeability, activation of the coagulation cascade, and necrosis of arterioles. Other hypertensive crises occur when the elevated blood pressure of patients with hypertension exacerbates injury to target organs; it often results in a pathologic feedback loop, which further elevates the blood pressure and exacerbates the damage.

PRESENTING SIGNS AND SYMPTOMS
Hypertensive disease occurs in organ systems in which injury to arterioles leads to ischemic damage or hemorrhage. These target organs include the brain, heart, blood vessels, and kidneys (Box 69.1). Therefore, the clinical history and physical examination must include an evaluation of these organ systems.
Hypertensive Crisis

Cerebrovascular decompensation is less likely. Hypertensive encephalopathy produces characteristic findings on computed tomography (CT). Scans show a posterior leukoencephalopathy that predominantly affects the white matter of the parietooccipital regions bilaterally. CT is useful in excluding other causes of altered mental status such as intracranial bleeding.

Accelerated-Malignant Hypertension

Accelerated-malignant hypertension occurs most commonly in young African American males with underlying renal parenchymal disease or renovascular disease. It is most commonly found in patients with long-standing hypertension and usually occurs without encephalopathy. When endothelial vasodilator responses are overwhelmed, further hypertension and endothelial damage occur and lead to inflammatory vasculopathy. Marked elevation in blood pressure and characteristic eyeground findings make the diagnosis. Flame-shaped hemorrhages develop around the optic disk because of the high intravascular pressure, and soft exudates are caused by ischemic infarction of the nerve fibers secondary to occlusion of the supplying arterioles. Common symptoms include headache (85%), visual blurring (55%), nocturia (38%), and weakness (30%). Laboratory evidence includes azotemia, proteinuria, hematuria, hypokalemia, and metabolic alkalosis. Papilledema is considered the sine qua non of malignant hypertension. Accelerated hypertension is used to describe the same condition (hemorrhages and exudates) without papilledema. Because the absence of papilledema does not connote a different clinical prognosis or therapy, the term accelerated-malignant hypertension is now recommended.

Differential Diagnosis

Persistently elevated blood pressure can trigger or exacerbate crises in these target organs. Rapid and progressive target organ damage secondary to severely elevated blood pressure defines a hypertensive emergency. Less commonly, hypertension is the primary crisis. Increasing systemic pressure causes an inflammatory endovasculitis; further damage and aggravation as a result of adrenergic stimulation and vasoconstriction accelerate the elevated blood pressure. The multiorgan disease resulting from an overwhelmed autoregulatory function is called malignant-accelerated hypertension. Inflammatory changes in the cerebral vasculature produce a serious alteration in mental status termed hypertensive encephalopathy. Primary and secondary hypertensive emergencies that must be included in the initial differential diagnosis are listed in Box 69.2.

Hypertensive Encephalopathy

The triad of severe hypertension, altered mental status, and (often) papilledema characterizes hypertensive encephalopathy, and it may be accompanied by lethargy, confusion, headache, visual disturbances, and seizures. Somnolence, stupor, and nausea or vomiting may also occur. Retinopathy may or may not be present. The mechanism of the disease is loss of autoregulation as a result of the cerebral overperfusion caused by profound hypertension; when the hypertension is controlled, the patient’s mental status improves. Persistent overperfusion results in vasodilation and increased permeability of cerebral blood vessels, which in turn leads to the development of cerebral edema. If not adequately treated, hypertensive encephalopathy can progress to cerebral hemorrhage, coma, and death.

Hypertensive encephalopathy is most likely to occur in previously normotensive individuals who experience a rapid rise in blood pressure, such as children with acute glomerulonephritis and young women with preeclampsia or eclampsia. Because chronically hypertensive patients usually experience a more gradual rise in blood pressure, cerebrovascular decompensation is less likely. Hypertensive encephalopathy produces characteristic findings on computed tomography (CT). Scans show a posterior leukoencephalopathy that predominantly affects the white matter of the parietooccipital regions bilaterally. CT is useful in excluding other causes of altered mental status such as intracranial bleeding.

Accelerated-Malignant Hypertension

Accelerated-malignant hypertension occurs most commonly in young African American males with underlying renal parenchymal disease or renovascular disease. It is most commonly found in patients with long-standing hypertension and usually occurs without encephalopathy. When endothelial vasodilator responses are overwhelmed, further hypertension and endothelial damage occur and lead to inflammatory vasculopathy. Marked elevation in blood pressure and characteristic eyeground findings make the diagnosis. Flame-shaped hemorrhages develop around the optic disk because of the high intravascular pressure, and soft exudates are caused by ischemic infarction of the nerve fibers secondary to occlusion of the supplying arterioles. Common symptoms include headache (85%), visual blurring (55%), nocturia (38%), and weakness (30%). Laboratory evidence includes azotemia, proteinuria, hematuria, hypokalemia, and metabolic alkalosis. Papilledema is considered the sine qua non of malignant hypertension. Accelerated hypertension is used to describe the same condition (hemorrhages and exudates) without papilledema. Because the absence of papilledema does not connote a different clinical prognosis or therapy, the term accelerated-malignant hypertension is now recommended.

CEREBROVASCULAR HYPERTENSIVE CRISIS
Hypertension frequently complicates the management of patients with cerebrovascular accidents (CVAs). After a CVA patients generally have focal neurologic deficits that are somewhat predictable based on the territory of the brain affected. A thorough neurologic examination can elucidate clues about the vessel in which flow has been disrupted either by occlusion or by hemorrhage. Ischemic strokes result from three major categories: thrombotic, embolic, and hypoperfusion. Compromised blood flow produces cell death at the center of the ischemic region and reversibly damaged neurons in the periphery, also known as the penumbra. The penumbra’s viability depends on its perfusion. Hemorrhagic stroke is caused by either intracranial or subarachnoid bleeding. Intracranial pressure (ICP) increases and cerebral perfusion pressure (CPP) is reduced at the site of the hematoma. Therefore, maintaining cerebral perfusion is key in both types of CVA, and an understanding of cerebrovascular physiology is helpful in determining the best treatment strategy.

Cerebral blood flow (CBF), a function of CPP, is equal to mean arterial pressure (MAP) minus ICP (CPP = MAP – ICP). The process of vasoconstriction and vasodilation of the cerebral vasculature maintains a steady CBF. However, cerebral autoregulation fails at approximately 25% above or below the patient’s usual MAP. In addition, changes in ICP or brain injury can result in loss of the brain’s ability to autoregulate blood flow. Increased ICP, commonly seen with hemorrhage or edema, decreases CPP and makes the brain more vulnerable to changes in MAP. In normal individuals, CBF remains fairly constant at MAP values of approximately 60 mm Hg up to 150 mm Hg. When MAP decreases to less than the lower limits of autoregulation, the brain becomes hypoperfused and cerebral hypoxia develops, with symptoms such as dizziness, nausea, and syncope. In chronically hypertensive individuals, the lower limit of autoregulation increases, and autoregulation might fail at MAP values that are well tolerated in nonhypertensive individuals. This suggests that chronically hypertensive patients cannot tolerate a rapid return to “normal” blood pressure and that MAP should be acutely decreased by no more than 20% to 25%.

CARDIOVASCULAR HYPERTENSIVE CRISIS
Hypertensive emergencies involving the heart and great vessels include congestive heart failure, acute coronary syndromes, and aortic aneurysm or dissection. Blood pressure is frequently elevated in patients with acute pulmonary edema, particularly when a high-output state is the cause, such as volume overload with renal failure, thyrotoxicosis, or severe anemia. Transient diastolic dysfunction, which may or may not be a direct result of the elevated blood pressure, also causes acute pulmonary edema with hypertension and congestive heart failure. Symptoms include tachypnea, tachycardia, pulmonary rales, jugular venous distention, and an S3 gallop.

Acute coronary syndromes are also frequently accompanied by hypertension. Reducing myocardial work by lowering blood pressure and the heart rate has been demonstrated to decrease infarct size in patients not receiving thrombolytic therapy. Classically, patients have symptoms of chest pain, dyspnea, diaphoresis, nausea, and light-headedness.

Acute aortic dissection is thought to occur as a result of aortic dilation or high blood pressure superimposed on a structural weakness of the arterial wall causing a tear in the intimal layer. Pulsatile pressure extends the dissection by separating the layers of the arterial wall. Historical series report a mortality of 1% to 2% per hour. The stresses that extend the dissection are thought to be related as much to the aortic pulse wave or pulse pressure (the difference between systolic and diastolic pressure over time) as it is to MAP. Heart rate, myocardial contractility, and MAP all contribute to increased pulse pressure. Affected patients include elderly persons with hypertension or atherosclerotic disease and individuals with connective tissue disorders. Hallmark symptoms are acute, severe retrosternal pain radiating to the back or intrascapular pain. Patients may have pulse deficits, neurologic symptoms, or ischemic symptoms in involved organs such as the gut, kidney, or heart.

RENOVASCULAR HYPERTENSIVE CRISIS
The kidney is unique in being both a target organ and the cause of many hypertensive emergencies. Hypertension causes 30% of cases of end-stage renal disease, which makes it the second most common cause after diabetes. Nephrosclerosis may develop in chronically hypertensive patients after 10 to 15 years and is manifested as damage to the medial layer of capillaries, reduced kidney size, and nonnephrotic levels of proteinuria without hematuria. By contrast, malignant hypertension damages the intimal layer of the renal capillary bed and may result in enlarged kidneys, cellular urinary sediment, hematuria, and severe proteinuria.

Severe hypertension in a young patient raises the possibility of intrinsic acute renal disease, such as glomerulonephritis. IgA nephropathy has surpassed poststreptococcal glomerulonephritis in frequency, and Henoch-Schönlein purpura is the most likely cause of acute glomerular disease in children. Renal artery stenosis is present in only 1% of unselected hypertensive patients but is seen in 4% of blacks and 32% of whites who have severe hypertension (diastolic blood pressure > 125 mm Hg with retinopathy). It is also more common in patients with a rapidly progressive course. Occasionally, devastating acute renal failure may occur as a result of intrarenal vasculitis. This is common in the setting of scleroderma and may be responsive to angiotensin-converting enzyme inhibitors (ACEIs).

CATECHOLAMINE EXCESS
The most familiar drugs found to cause hypertension in EDs today are sympathomimetic drugs such as phenylephrine, cocaine, and methamphetamine. Tyramine can induce a hypertensive crisis in patients taking a monoamine oxidase inhibitor, and hypertension can complicate withdrawal syndromes from alcohol, benzodiazepines, clonidine, and beta-blockers. Pheochromocytoma can cause intermittent hypertensive crisis.
and may be responsible for many clinical findings besides hypertension, such as headache, sweating, palpitations, pallor, nausea, and rarely, seizures. Some patients with pheochromocytoma may have paroxysms of low blood pressure as well.

**Hypertensive Crisis**

Third trimester emergencies are addressed separately in Chapter 121. Emergencies include eclampsia and preeclampsia. Pregnant women between 20 weeks’ gestation and 2 weeks postpartum who have any degree of hypertension (≥140/90 mm Hg) or an increase of more than 30/15 mm Hg above their baseline blood pressure, accompanied by peripheral edema and proteinuria, have preeclampsia. Hypertension is important mainly as a symptom of the underlying disorder rather than as a cause. Preeclampsia is essential to recognize because it can progress suddenly to eclampsia, defined by the occurrence of convulsions. Additional symptoms include headache, visual changes, epigastric pain, oliguria, facial and extremity edema, and HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count). Eclampsia can rapidly progress to coma or death. Magnesium infusion is more effective than other anticonvulsants in this setting. Because definitive treatment consists of delivery of the fetus, the emergency physician (EP) usually collaborates with an obstetrician early in the patient’s course through the department.

**MEDICAL DECISION MAKING**

EPs evaluate and treat hypertension in a variety of contexts ranging from compliant patients with well-controlled blood pressure, to asymptomatic patients with increased blood pressure, to critically ill patients with increased blood pressure and acute target organ deterioration. Many patients with severely elevated blood pressure have a combination of long-standing, poorly treated hypertension and acute aggravating conditions such as pain, anxiety, or intoxication. Though a major public health risk, elevated blood pressure is rarely a crisis in the ED. Evidence-based national guidelines exist for the evaluation and treatment of hypertension\textsuperscript{15,16} but there is no good evidence to guide the acute treatment of a patient with severely elevated blood pressure. Instead, the EP relies on an understanding of the disease process, its associated complications, and the health care support available to the patient.

Patients often have elevated blood pressure and nonspecific symptoms. The EP must make a prospective decision about the cause of the symptoms to determine management of the blood pressure. If a hypertensive patient’s chest pain is possibly anginal, immediate parenteral control might be necessary. However, if the EP determines that the pain is not cardiovascular in origin, the same patient might not need immediate treatment of the elevated blood pressure. Findings on assessment of the patient determine the need for treatment.

The concept of hypertensive urgency, which refers to markedly elevated, asymptomatic blood pressure requiring rapid intervention, is no longer widely used. Most patients without acute, progressive target organ disease can have their severely elevated blood pressure managed on an outpatient basis. However, certain patients are at higher risk for near-term complications from their uncontrolled hypertension. This group includes the elderly or frail and especially those with a history of previous end-organ disease (e.g., history of stroke, heart failure, renal insufficiency). These patients do require increased vigilance and possibly aggressive intervention.

**DIAGNOSTIC TESTING**

The nature, severity, and management of hypertensive crises are determined by clinical evaluation. When a patient with markedly elevated blood pressure is seen in the ED, accurate measurement of blood pressure is the first step. Blood pressure that is initially elevated in the ED frequently decreases spontaneously by the time that a second reading is obtained.\textsuperscript{17,18} Any intervention should be based on the composite of several repeated blood pressure measurements. To obtain an accurate measurement, the patient should be seated with the arm at the level of the heart and at least 80% of the arm circumference covered with the cuff bladder. Pressure is evaluated in both arms. Blood pressure measurement with an automated cuff may be inaccurate in patients with atrial fibrillation and other heart rhythm irregularities. Appropriate pain management and relief of the underlying cause (e.g., hypoxia, bladder distention) may resolve the hypertension. Certain medications, over-the-counter preparations, or illicit drugs may transiently exacerbate hypertension (Box 69.3).

**TIPS AND TRICKS**

Elevated triage blood pressure readings often spontaneously improve without treatment. Always recheck abnormal readings.

An initially elevated blood pressure might resolve with proper cuff size or treatment of pain, urinary retention, or hypoxia.

If no emergency is anticipated and immediate parenteral therapy is not required, patients should be given a dose of the medications that they were supposed to have taken so that some effect has occurred if and when they are ready to be discharged.

Become comfortable with a small number of parental agents; in most instances any one will work.

Elicit a history of use of cocaine or other sympathomimetic drugs.

**BOX 69.3 Medications That Can Elevate Blood Pressure or Interfere with the Effectiveness of Antihypertensive Agents**

- Oral contraceptives
- Steroids
- Nonsteroidal antiinflammatory drugs
- Nasal decongestants
- Cold remedies
- Appetite suppressants
- Tricyclic antidepressants
- Monoamine oxidase inhibitors
If the patient’s blood pressure is persistently elevated, elicitation of the history should start with an assessment of symptoms that might be consistent with target organ compromise. Details include the duration and severity of preexisting hypertension, success with previous blood pressure regimens, and any history of target organ disease (cardiovascular, cerebrovascular, renovascular, and great vessel). Physical examination should be directed toward identifying signs of target organ damage. Funduscopic examination showing retinal hemorrhage or papilledema is sufficient to diagnose accelerated-malignant hypertension. The cardiovascular examination focuses on identifying signs of heart failure (e.g., increased jugular venous pressure, pulmonary rales, and S3 heart sound). The neurologic examination assesses the level of consciousness, visual fields, and the presence of focal motor and sensory deficits.

The patient’s symptoms direct the EP’s diagnostic evaluation. For example, dyspnea or signs of heart failure are an indication for a chest radiograph, and neurologic findings are an indication for CT of the head. Box 69.1 summarizes some common symptoms and their associated end-organs. Few studies have assessed the prognostic value of laboratory testing in asymptomatic patients with severely elevated blood pressure.19 However, asymptomatic patients with blood pressure persistently higher than 180/110 mm Hg warrant a brief assessment of target organ function (Fig. 69.1). Because renal failure is silent, measurement of serum creatinine or urinalysis (or both) for evidence of renal failure or nephritis is reasonable. An electrocardiogram (ECG) is useful in assessing the baseline level of left ventricular hypertrophy, ischemia, or infarction. The presence of left ventricular hypertrophy on an ECG carries a poor prognosis and necessitates a more vigilant

---

**Fig. 69.1 Management of patients with severely elevated blood pressure (BP).** BUN, Blood urea nitrogen; CHF, congestive heart failure; CRI, chronic renal insufficiency; CVA, cerebrovascular accident; DBP, diastolic BP; ECG, electrocardiogram; ED, emergency department; MAP, mean arterial pressure; MI, myocardial infarction; Rx, therapy; SBP, systolic BP; UA, urinalysis.
follow-up. When renovascular disease or hypercortisolism is suspected to be a cause of the hypertension, serum should be drawn to determine plasma renin activity and aldosterone levels before administering medications. A urine screen for cocaine and amphetamines may help confirm extrinsic causes of the elevated blood pressure. The value of obtaining a chest radiograph or a complete blood count in patients in the ED without relevant symptoms is likely to be low.

**TREATMENT**

**PREHOSPITAL MANAGEMENT**

To date, the role of prehospital treatment of hypertension or hypertensive emergencies is minimal. Hypertension complicating angina or pulmonary edema should be treated with nitrates (other medications are not time critical if transport time is brief). Emergency medical service providers should not lower blood pressure in patients with a possible stroke because of the possibility of extending the ischemic region.

**HOSPITAL MANAGEMENT**

Ideally, ED management of hypertensive crises would entail the administration of fast-acting, rapidly reversible medications that can easily be titrated to the desired effect of a 20% decrease in MAP. No single agent is optimal in all cases of hypertensive crisis. The agent of choice and the manner of administration depend on the severity of the blood pressure abnormality, the severity and type of end-organ dysfunction present, and the clinical findings.

**HYPERTENSIVE EMERGENCY**

The goal of therapy in patients in hypertensive crisis is a 20% to 25% reduction in MAP over a period of 1 to 2 hours. The ideal drug for treating hypertensive emergencies would easily titrate blood pressure through rapid onset, rapid maximal effect, and rapid offset. These characteristics are found only in parenteral agents. Table 69.1 summarizes the most commonly used medications and doses.

Nitroprusside is the classic agent for the treatment of patients with hypertensive emergencies. Nitroprusside decreases both preload and afterload without significant reflex tachycardia through arteriovenous vasodilation. It has a quick onset of action, and its effect lasts for only 2 to 5 minutes after use of the drug is discontinued. Hemodynamics must be monitored closely to prevent inadvertent hypotension. Thiocyanate toxicity may occur if the drug is administered for more than 48 to 72 hours, particularly in patients with renal failure. It is contraindicated in pregnancy. Because no oral form is available, the patient must be switched to a different antihypertensive once control is achieved. Despite the many benefits of nitroprusside, other agents are often better suited for individual hypertensive crises.

Nicardipine is a rapidly acting parenteral calcium channel blocker. It has a predictable and smooth onset of action, but it is relatively long acting. Esmolol is a beta-blocking agent that is both rapid in onset and of short duration, thus making it easy to titrate. Labetalol, an easily titratable medication, combines alpha- and beta-blockade, which makes it more potent than esmolol. Comparatively, labetalol maintains a more consistent CPP and has a longer half-life. This enables the administration of miniboluses instead of a constant infusion but makes it more difficult to titrate downward. Caution is advised when administering beta-blockers to patients with asthma, chronic obstructive pulmonary disease, acute congestive heart failure, cocaine abuse, or other contraindications to beta-blockade. Fenoldopam is a parenteral dopaminergic receptor blocking agent with an excellent efficacy and safety profile. Fenoldopam holds some promise as being equivalent to nitroprusside in efficacy without the rare side effects associated with nitroprusside’s cyanide moiety and perhaps with less overshoot hypotension, but it is costly. Other options include enalaprilat, a parenteral ACEI, and phentolamine, a pure alpha-blocking agent.

**CEREBROVASCULAR CRISIS**

Blood pressure control should be undertaken with caution in patients with cerebrovascular hypertensive emergencies. Parenteral drugs that have a short half-life, are easily titrated, and have minimal effect on the cerebral vasculature are ideal. Because labetalol does not dilate cerebral capacitance vessels, it is theoretically attractive in patients with intracerebral disorders. Caution should be used with direct vasodilators such as nitroprusside in patients with focal brain injury because they can extend an area of ischemia. Although nicardipine is safe and widely used, other calcium channel blockers have been linked to a rise in ICP and are therefore not favored in patients with brain injury.

Treatment of elevated blood pressure in the setting of ischemic CVAs is controversial. When systemic blood pressure is reduced, cerebral autoregulation may fail, thereby extending the ischemic penumbra surrounding the infarct and leading to extension of the stroke. Alternatively, infarction may lead to edema, elevated ICP, and a further reduction in CBF. The current American Stroke Association guidelines recommend lowering blood pressure in patients with stroke only when MAP is greater than 130 mm Hg or systolic blood pressure is greater than 220 mm Hg.

Theoretically, treatment of elevated blood pressure in patients with hemorrhagic CVAs and subarachnoid hemorrhage should be more aggressive than in patients with ischemic strokes. The rationale is to decrease the risk for ongoing bleeding from ruptured small arteries and arterioles; however, the relationship between rebleeding and systemic blood pressure is unproven. As with ischemic CVAs, overly aggressive treatment of hypertension may worsen brain injury by decreasing CPP when ICP is increased. The American Stroke Association guidelines for blood pressure control in patients with hemorrhagic stroke are similar to those for ischemic stroke: blood pressure should be lowered only when MAP is greater than 130 mm Hg or systolic blood pressure is greater than 220 mm Hg. Nimodipine, an oral calcium channel blocker, may be administered to decrease the incidence of vasospasm and rebleeding after subarachnoid hemorrhage, but the drug is not recommended for blood pressure control.

**CARDIOVASCULAR CRISIS**

Nitroglycerin (NTG) is favored for the treatment of severe hypertension complicating cardiac ischemia. NTG is a direct vasodilator that affects the venous more than the arterial vasculature. NTG dilates the coronary arteries and, in contrast to nitroprusside, promotes a favorable redistribution of blood flow to ischemic areas. Beta-blockers are also effective and
recommended therapy for acute coronary syndromes. The goal of treatment in patients with acute coronary syndromes is reduction of blood pressure to normal if evidence of ischemia persists. However, careful blood pressure reduction requires intensive patient monitoring; overly vigorous lowering of blood pressure may worsen the ischemia because coronary perfusion depends on diastolic blood pressure.

Most critical cases of congestive heart failure are treated with a combination of NTG, furosemide, and an ACEI. For patients with pulmonary edema and hypertension, sublingual NTG should be initiated while preparing intravenous NTG. Captopril should be administered orally or sublingually or enalaprilat administered intravenously. If systemic fluid overload is present, intravenous furosemide should be administered. However, up to 25% of patients with heart failure and severely elevated blood pressure may have “dry failure” in which pressure natriuresis makes them fluid depleted. Further diuresis may exacerbate the process and continue to stimulate

†Hypotension may occur with all agents.
‡Requires a special delivery system.
the renin-angiotensin axis. The decision should be based on clinical judgment of whole-body fluid status. Although beta-blockers have been found to improve survival in patients with chronic congestive heart failure, use in patients with acute pulmonary edema may precipitate immediate worsening because of their negative inotropic effects and bradycardia. Intravenous nesiritide improves hemodynamic function and symptoms in patients with decompensated heart failure and has a modest anti hypertensive effect, but it has not been well studied in the setting of hypertensive crisis.

With aortic dissection, progression of the vascular injury is dependent not only on the elevated blood pressure but also on the aortic ejection velocity or tachycardia-induced shear forces. Therefore, a rate-controlling agent such as esmolol should be initiated before starting nitroprusside to avoid the effects of reflex tachycardia. Alternatively, labetalol, nicardipine, or fenoldopam has been suggested as possible substitutes for nitroprusside. Labetalol achieves its maximal effect within minutes and then remains effective for several hours, thus allowing titration with small boluses and avoiding the constant monitoring and increased cost required with nitroprusside. Nicardipine and fenoldopam are vasodilators that would require the intensive monitoring needed with nitroprusside but are less toxic alternatives.

RENOVASCULAR CRISIS

When compared with nitroprusside, fenoldopam may improve outcomes in patients with hypertension and acute renal failure. Even though malignant hypertension may precipitate acute renal failure by injuring the kidney’s microvasculature, this causal chain is often reversed with chronic renal failure when long-term renal damage is manifested as severe hypertension. Because this distinction cannot be made in the ED, all these patients should have their blood pressure lowered. Both nitroprusside and labetalol are excellent choices in this setting. Although ACEI drugs definitely improve the prognosis of patients with chronic hypertension and mild proteinuria, they should be used cautiously in hypertensive patients with acute uremia. Nitroprusside may cause thiocyanate poisoning over a period of several days in patients with renal failure; it should be used only if it briefly or if the patient will undergo dialysis soon.

Treatment with an ACEI may reverse high blood pressure dramatically in patients with unilateral renal artery stenosis, but it may provoke acute renal failure and severe hyperkalemia in patients with bilateral stenosis, particularly if they are taking supplemental potassium or a potassium-sparing diuretic. This complication can be completely reversed by discontinuing the ACEI.

CATECHOLAMINE EXCESS

Patients with severe hypertension secondary to pheochromocytoma are treated with the pure alpha-blocker phentolamine administered intravenously. It may be accompanied by a beta-blocker if needed for tachycardia. Administration of beta-blockers alone in the setting of any sympathomimetic (e.g., cocaine) may leave the alpha receptors “open,” with subsequent worsening of the hypertension. Thus, an attractive alternative to beta-blockers is labetalol, a beta-blocker with some alpha-antagonist properties. However, the alpha- and beta-blockade with labetalol may not be equally effective. Additionally, benzodiazepines are useful adjuncts in patients with cocaine-induced catecholamine excess. They decrease both the central and peripheral sympathomimetic outflow stimulated by cocaine, thereby lowering the heart rate, psychomotor hyperactivity, and blood pressure.

HYPERTENSION IN PREGNANCY

The mainstay of antihypertensive treatment of pregnant patients in hypertensive crisis in many institutions is hydralazine administered intravenously in boluses of 5 to 10 mg every 20 to 30 minutes. This is in addition to magnesium therapy for control of seizures. If the hypertension is refractory to hydralazine, second-line agents are diazoxide and beta-blockers. Calcium channel blockers have been studied in pregnant patients with chronic hypertension, but they may not be effective in treating proteinuric hypertension.

CONSULTATION

Hypertensive emergencies require admission to a monitored setting. These patients generally require emergency involvement of an appropriate specialist for management of a neurologic, cardiovascular, or renovascular crisis. Close blood pressure monitoring, preferably with an arterial line, is indicated. Patients with preeclampsia or eclampsia require emergency obstetric consultation.

Uncontrolled hypertension causes profound and irreversible internal injuries over the long term, many of which are asymptomatic. Transient blood pressure elevation is rarely dangerous, and management decisions must be based on evidence of extended hypertension. There are many medications with different convenience and side effect profiles that the primary care provider can substitute to find a good match. Adherence to a medication regimen is essential for healthy living. Chest pain, difficulty breathing, severe and new headaches, and focal numbness or weakness are possible signs of heart or brain injury and should be evaluated by a doctor immediately.

NEXT STEPS IN CARE AND ADMISSION

All hypertensive patients with evidence of end-organ dysfunction require hospitalization for management of their blood pressure, treatment of their organ dysfunction, and consultation with appropriate specialists.

Most patients with elevated blood pressure are not in crisis. Very few asymptomatic patients with markedly increased blood pressure will experience a near-term adverse event. Very high blood pressure might be seen in chronically hypertensive patients as a consequence of discontinuing previous therapy or as a result of other easily reversible causes, such as anxiety, pain, drug use, or change in diet. No evidence
BOX 69.4 Initial Drug Choices for Hypertension

Use unless contraindicated. Start with a low dose of a long-acting once-daily drug and titrate the dose; low-dose combinations might be appropriate.

**Uncomplicated Hypertension**
- Diuretics
- Beta-blockers

**Diabetes Mellitus (Type 1) with Proteinuria**
- Angiotensin-converting enzyme (ACE) inhibitors

**Heart Failure**
- ACE inhibitors
- Diuretics

**Isolated Systolic Hypertension (Older Person)**
- Diuretics preferred
- Long-acting dihydropyridine calcium antagonist

**Myocardial Infarction**
- Beta-blockers (without intrinsic sympathomimetic activity)
- ACE inhibitors (with systolic dysfunction)

has shown that the absolute level of a patient’s blood pressure warrants immediate or aggressive treatment. Rather, in patients with asymptomatic, elevated blood pressure and no evidence of target organ disease, the most important intervention is to ensure proper follow-up. The goal should be lifelong control of the blood pressure.

When the elevated blood pressure may be the artifact of a systemic process such as pain or infection, the best strategy is to refer the patient for reevaluation of the blood pressure once the primary problem has resolved. If the patient has discontinued the blood pressure medications, the regimen should be restarted, barriers to compliance evaluated, and a primary care physician contacted to ensure reevaluation in a week. The hypertension guidelines recommend a thiazide-type diuretic as an initial agent, usually in combination with a drug from another class.15 The second agent may be from a number of categories and is best chosen in accordance with any compelling indications in the patient’s history (Box 69.4).

In principle, in individuals without a previous measurement of elevated blood pressure, the blood pressure needs to be rechecked at another visit before the diagnosis of hypertension can be made. However, in individuals with readings persistently higher than 180/110 mm Hg in the ED, the latest national guidelines recommend that combination therapy be started immediately (same day).15 In the best scenario, the EP contacts a primary physician for the patient, who then selects an initial antihypertensive agent or agents and provides follow-up within about a week.

An intermediate group of patients has severely elevated blood pressure and known target organ disease but no active decompensation. An example is a severely hypertensive patient with a previous history of myocardial infarction or stroke. Immediacy arises because a patient with known target organ disease may be considered at higher risk for a hypertension-related adverse event in the short term. However, there is no good evidence base for the best management of these patients. A treatment strategy should be initiated in the ED, although blood pressure does not necessarily need to be lowered during the visit. These patients do require an increased level of vigilance. It may be reasonable to treat them as outpatients, although some may need to be held for short-term observation if their medication compliance or blood pressure monitoring is uncertain; the decision depends on clinical judgment (see Box 69.5).

In practical terms, hypertensive emergencies require an immediate (within 1 to 2 hours) decrease in blood pressure, hypertensive urgency requires initiation of a strategy to decrease and monitor blood pressure over a 24- to 48-hour period, and uncontrolled severe hypertension requires therapy to decrease blood pressure within 1 week. Stratification within these categories involves careful clinical evaluation and understanding of target organ disease and treatment strategies.

**BOX 69.5 Discharge Criteria for “Hypertensive Urgency”**

1. Likely to be compliant with established primary care
2. Known to have hypertension
3. Reversible precipitating cause (e.g., medication noncompliance, adverse drug effect)
4. Able to resume a previously effective medication regimen
5. Can be seen for follow-up within 7 days.

**PRIORITY ACTIONS**

**Severely Elevated Blood Pressure**
- Recheck the patient’s blood pressure with the correct method in both arms.
- Evaluate and treat aggravating conditions (e.g., pain, anxiety, intoxication).
- Evaluate for evidence of target organ damage.
- Elicit a history of target organ disease.
- Administer therapy based on the underlying pathology.
- Reevaluate continuously for signs of response to therapy or deterioration.

**RED FLAGS**

Diagnosing a hypertensive emergency when one does not exist. Patients with hypertensive emergencies have evidence of acute end-organ dysfunction.

Reducing blood pressure too quickly or to too low a level in patients with chronic hypertension whose autoregulation curve has been reset can lead to cerebral or cardiac ischemia.

Lowering a patient’s blood pressure acutely without an urgent indication.

Failing to diagnose hypertension or preeclampsia in pregnant patients with blood pressures higher than 140/90 mm Hg or with an increase in blood pressure of more than 30/15 mm Hg.

Neglecting to match the antihypertensive agent to the clinical scenario.
CHAPTER 69  HYPERTENSIVE CRISIS

DOCUMENTATION

Be sure that any elevated blood pressure is noted and addressed.
Be sure to document any change in blood pressure with treatment.
Document possible causes of the elevated blood pressure.
List any past medical history of target organ disease.
List current antihypertensives and any recent changes in medications or noncompliance.
Document the presence or absence of end-organ dysfunction found during assessment of the patient’s elevated blood pressure.
Document patient counseling for medications, reasons to return, and primary care follow-up.

Pulmonary Embolism

D. Mark Courtney

KEY POINTS

- Appropriate testing for pulmonary embolism (PE) requires both an understanding of the pretest probability for each individual patient and knowledge of the characteristics of the diagnostic test used at your specific institution.
- A pretest probability of less than 10% with a negative D-dimer result that has a sensitivity of at least 95% is sufficient to rule out PE in most clinical circumstances.
- Right heart strain on an echocardiogram or electrocardiogram, decreased oxygen saturation, elevated brain natriuretic peptide, and elevated troponin may predict a worse short- and long-term outcome in patients in whom PE is diagnosed.
- Treatment of PE consists of heparin and initiation of warfarin to prevent additional clot formation.
- Treatment of shock associated with PE includes intravenous fluid, vasopressors, respiratory support, and thrombolytic therapy.
- PE represents a spectrum of severity determined by the size of the clot and baseline cardiopulmonary disease.
- The probability of mortality increases steeply once right ventricular dysfunction and hypotension occur.
- Diagnosis of PE as a cause of shock requires consideration of PE as a potential cause and a stepwise approach to simultaneous testing and resuscitation.

EPIDEMIOLOGY

The annual incidence of diagnosed pulmonary embolism (PE) is approximately 1.5 new cases per 1000 persons and is relatively similar among Western populations. Dyspnea and chest discomfort are the most typical symptoms of PE, and these chief complaints are responsible for between 9 and 10 million annual patient visits to U.S. emergency departments (EDs). Physicians evaluate large numbers of patients for PE because the symptoms can be vague and severity may range from asymptomatic to shock and subsequent cardiac arrest.

The widespread availability of D-dimer and computed tomography (CT) testing for PE, as well as medical-legal concerns of missing the diagnosis, continues to result in dramatic increases in testing relative to the last decade. In some settings it is not uncommon for 1% to 3% of all adult ED patients to undergo some testing for PE. Physicians have become aware that patients without what was previously thought to be “classic” risk factors (hypercoagulability, trauma, and immobility) may still have PE. In addition, the aging demographics of the U.S. population will continue to drive the need to evaluate for PE in the ED because increased age is a strong independent risk factor for PE. To deal with these challenges, the practicing physician has three aims:

1. Recognize the potential for PE to exist in the appropriate settings
2. Perform the optimal test based on pretest probability and specific test characteristics
3. Be capable of estimating the prognosis for each patient after the diagnosis is made and institute appropriate therapy

PATHOPHYSIOLOGY

PE is part of the continuum of venous thromboembolism (VTE), which most often starts with deep vein thrombosis (DVT) in the leg. Patients with DVT often have concurrent PE when evaluated with imaging tests, and many patients with PE have concurrent DVT. Treatment is similar for both. Risk factors for VTE include the triad described by Virchow: injury, venous stasis, and hypercoagulability. These conditions are most commonly thought of as occurring at the level of the venous endothelium, but it is helpful to also think of them as occurring at the level of the patient. For instance, overall injury to the patient (trauma), stasis of the patient (immobility), and hypercoagulability of the patient (malignancy and known thrombophilic conditions) all result in elevated risk. Table 70.1 lists several risk factors for VTE. Understanding risk factors is critical to recognizing the potential for PE to exist.

An embolus in the pulmonary vasculature may result in a large bilateral central clot with severe obstruction of flow (so-called saddle embolism), a medium clot in the lobar or segmental branches, or a small clot in the peripheral vasculature. Embolism involving the pulmonary vasculature activates the process of local inflammation and thereby leads to vasoconstriction and some degree of pulmonary hypertension with resultant symptoms of dyspnea and possibly chest pain.

CVA, Cerebrovascular accident; DVT, deep vein thrombosis; MI, myocardial infarction; PE, pulmonary embolism; VTE, venous thromboembolism.

Presenting Signs and Symptoms

Dyspnea and chest pain are the most common findings in patients with PE. Brief, resolved chest pain in the absence of any shortness of breath or any respiratory signs or symptoms is not a typical manifestation. Other symptoms that can be associated with PE include syncope, cough, flank pain, abdominal pain, and even fever (Box 70.1). The severity of symptoms in a given patient is a function of two factors: the baseline cardiopulmonary status of the patient and the size of the clot (Fig. 70.1). This is why large clots are occasionally tolerated fairly well in young patients with no cardiopulmonary disease whereas a much smaller clot burden may result in hypotension, hypoxemia, and deterioration in patients with preexisting cardiopulmonary disease. Older patients often have a worse clinical course and outcome with PE, largely as a consequence of having worse cardiopulmonary status at baseline rather than simply being elderly.

Shock may be a primary sign of PE. Patients may not be able to provide a history of symptoms or risk factors for PE and may not be sufficiently stable to allow imaging outside the ED, yet consideration of empiric treatment of PE with anticoagulation may be warranted. A rapid bedside evaluation to search for clues to non-PE diagnoses can be done promptly and is described in Figure 70.2. A potential pitfall is to attribute shock to a primary
cardiac etiology despite an electrocardiogram (ECG) with no significant ischemic changes and no significant dysrhythmia and a chest radiograph with no evidence of pulmonary vascular congestion or cardiomegaly. If patients can be stabilized, imaging with CT should be done. If not, emergency bedside echocardiography to look for signs of massive PE (right ventricular dilation and hypokinesis, septal shift to the left, tricuspid regurgitation) should be done as an alternative means of heightening certainty of the diagnosis of PE.

The other end of the spectrum is the diagnosis of PE in patients with relatively mild symptoms. Despite the fact that patients may have PE with normal oxygen saturation, no known risk factors, and no pulmonary symptoms, this combination is uncommon. Strict attention to details such as oxygen saturation after walking, physician-obtained respiratory rate, examination of the legs, and serial assessment may help either reassure physicians that patients have such a low probability of PE that testing is unwarranted or provide evidence to justify an evaluation for PE.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Because of the vague yet common nature of dyspnea and chest pain, the differential diagnosis is broad. However, a targeted diagnostic approach should be used rather than a “chest pain work-up” in an attempt to test for every diagnosis possible without regard to the pretest probability or negative consequences of overtesting. This is particularly important for PE because tests are not 100% sensitive or specific and the consequences of a false-positive diagnosis may include 6 months of oral anticoagulation with high direct and indirect costs to the patient and society. This is especially true in young patients with limitations in activity, as well as in older patients at risk for falls, medication interaction, and bleeding. Table 70.2 lists potential alternative diagnoses in ED patients evaluated for PE and clues to assist in rapid decision making. It is not

surprising that many of these conditions are common entities such as pneumonia, bronchitis, asthma, musculoskeletal pain, gastroesophageal reflux or spasm, and anxiety or panic attack. Many of the most threatening alternative diagnoses can initially be evaluated with a chest radiograph, an ECG, bedside cardiac ultrasound, and cardiac enzyme testing during the first hour in the ED.

It is most helpful to think of PE as a continuum of cardiovascular stress as shown in Figure 70.1. Even in normotensive patients, in-hospital or 30-day mortality in those with diagnosed PE is approximately 8% to 13%.3-9 This mortality in PE patients without shock is greater than that for acute myocardial infarction.10 When early signs of right heart dysfunction occur, mortality begins to curve upward. This is followed by compensated shock, which may initially respond to intravenous fluid. Later, as left-sided filling is decreased because of septal shift into the left ventricle, as well as decreased filling of the left atrium, overt shock is present and mortality is in excess of 30%. If untreated, cardiac arrest ensues, with pulseless electrical activity being the most likely first rhythm.11,12

With a score of 4 or less, the pretest probability is 5% or less; with a score higher than 4, the pretest probability is greater than 5%.

Other factors to consider include estrogen use (oral contraceptive pill or hormone replacement therapy), thrombophilic condition, pleuritic nature of the chest pain if present, family history of PE or DVT, and oxygen saturation lower than 95%.

DVT, Deep vein thrombosis; PE, pulmonary embolism.

### Diagnostic Testing

Pretest probability is the probability that the physician believes to be present before any test results are obtained. It is typically calculated by either a scoring system or the physician’s own “gestalt” estimation. Despite the fact that debate exists over the relative accuracy of using gestalt versus a structured means of assessing pretest probability, the American College of Emergency Physicians practice guideline of 2003 recommended pretest probability assessment in patients being evaluated for PE.13

The main structured pretest probability system with the longest track record of use and investigation is the Canadian score derived by Wells et al., which results in a score for an individual patient that can be used to estimate ranges of pretest probability14 (Table 70.3 and Fig. 70.3). Widespread clinical application of this scoring system can be challenging because of difficulty in physician recall15 and the fact that it provides a range of probability rather than an exact estimate. An alternative to these structured pretest probability systems is unstructured or implicit estimation systems whereby physicians arrive at their own pretest probability based on their experience and overall integration of clinical information for a unique patient. This is commonplace but imprecise and subject to wide variability.16 Recent data from a large multicenter study of ED patients in the United States found that several variables not in the Wells score may be significantly associated with the outcome of PE in ED patients who are tested. These variables are noted in Figure 70.3 and may be important in addition to the Wells score in formulating overall pretest probability.17

The most typical approach to testing for PE is to determine whether the pretest probability is sufficiently low (Wells score ≤ 4 or physician’s gestalt of “low risk”) and then to use a sensitive D-dimer blood test that detects the presence of fibrin breakdown products (see Fig. 70.3). If D-dimer is normal in
individual tests will vary in their actual sensitivity, specificity, and likelihood ratio, thus emphasizing the importance of clinician knowledge of the specific test at their institution.

Unfortunately with these tests, 20% to 40% of positive results may be falsely positive because of the low specificity of these blood tests. These patients require confirmation of the presence or absence of PE with an imaging test, usually a CT scan of the pulmonary arteries or a ventilation-perfusion (V/Q) scan. If imaging tests are negative in these low-risk patients, PE can be considered to be sufficiently excluded.

Fig. 70.3 Typical algorithmic approach to ruling out pulmonary embolism (PE). BNP, B-type natriuretic peptide; CT, computed tomography; DVT, deep vein thrombosis; ECG, electrocardiogram; V/Q, ventilation-perfusion.

these low-risk patients, the posttest probability of PE is below a sufficient test threshold (<1% to 2%), and PE can be considered to be sufficiently excluded in these patients. Typically, two types of D-dimer tests are available for ED testing: (1) quantitative tests, including enzyme-linked immunosorbent assay or immunoturbidimetric tests, which are considered to be abnormal at a particular cutoff, typically ≥500 ng/mL, and (2) qualitative whole blood agglutination or immunofiltration tests, which yield a binary result of positive or negative. Benefits of the quantitative tests include higher sensitivity. Benefits of the qualitative tests include rapid results because of bedside testing. Table 70.4 describes how the two different types of D-dimer tests may be used to rule out PE. These are estimates of diagnostic test performance, and
from the osmotic effects of contrast agents; concerns in pregnant patients; and the overall safety of leaving the ED when initiating testing for PE.

For these reasons, as well as the significant negative impact that a false-positive diagnosis may have for the patient because of months of anticoagulation, attempts to reduce testing in low-risk settings have been proposed. One such method is the PE rule-out criteria shown in Box 70.2.21 It was derived from a multicenter U.S. sample and provides simple, easy-to-apply clinical criteria that when satisfied, indicate that the baseline probability of PE is below a test threshold (<1.8%) and testing in this setting may be more likely to lead to patient harm than benefit. This is only an attempt to support clinician judgment when the probability of PE is already very low and it is not intended to replace or dictate individual patient-based decision making. Patients who meet the PE rule-out criteria but for other reasons are thought to need testing for PE should undergo the standard evaluation.

CT has largely supplanted the use of V/Q scans because of the perception that they produce a binary positive/negative result, as well as the fact that other chest pathology may be seen with CT.21 The sensitivity and specificity of chest CT angiography have improved with the advent of multidetector CT with higher spatial resolution and lower image acquisition time. Overall, well-accepted sensitivity and specificity data are lacking because of diverse differences in the equipment used, image acquisition technique, and image interpretation, but spiral CT is generally regarded to have greater than 90% sensitivity and specificity. One systematic review based on 3500 patients in 15 studies reported a pooled negative predictive value of 99.1% and a likelihood ratio for a negative result of 0.07. Newer CT scan machines with 128 detector systems and sophisticated image postprocessing will become more commonplace and improve the diagnostic accuracy of current imaging. Even with these newer machines, motion artifact, inadequate contrast bolus timing, and varied experience of readers may result in a surprising level of indeterminate or nondiagnostic results.22 Pretest probability assessment and D-dimer testing will still be important to avoid unnecessary radiation exposure and possible false-positive CT results in a large number of patients who have a very low likelihood of PE.

V/Q scanning is an alternative to CT for patients with contrast allergy or renal insufficiency and for pregnant patients. It is important to remember that patients who are found to be at high risk by pretest probability assessment and have low or indeterminate V/Q scans cannot be assumed to have PE ruled out. These patients need anticoagulation and further testing—typically, duplex Doppler ultrasound of the lower extremities.

Controversy exists regarding the optimal approach in pregnant patients. The estimated radiation dose from CT of the chest is low (7 to 14 millisieverts), and with shielding of the abdomen and pelvis, only a small fraction of this dose would be expected to be received by the fetus. It would be expected to be significantly lower than the threshold of teratogenicity. However, no prospective longitudinal data exist to clearly know what the optimal strategy should be or what the long-term risk is. V/Q scans have been used over a long period in pregnant patients and are thought to provide minimal to no risk to the fetus. However, the need for experienced technicians and experienced nuclear medicine physicians may limit the availability of V/Q scans. Regardless of what imaging method is available or chosen, it is important to minimize the amount of potential radiation received by the fetus. Discussion with the patient, obstetrician, radiologist, and family needs to occur at the outset even before tests are ordered and should include comment on the probability of disease, extremely low probability of radiation-associated negative effects, and potential morbidity with undiagnosed PE. Tests should be performed if appropriate concern exists for PE. The use of D-dimer is problematic in pregnant patients because the likelihood of a false-positive D-dimer result increases with progression of the pregnancy. It has been advocated that an elevated cutoff for quantitative D-dimer in a low-risk patient may be adequate to rule out PE. However, no prospective management trials exist to clarify a potential role of D-dimer in pregnancy. If used in early pregnancy, when the likelihood

**Box 70.2 Pulmonary Embolism Rule-Out Criteria**

If all the criteria below are met, the probability of PE is below a test threshold of 1.8% and testing may be more harmful than beneficial.

- Age < 50
- Pulse < 100 beats/min
- Oxygen saturation > 94%
- No hemoptysis
- No clinical evidence of DVT
- No hormone use
- No recent surgery or trauma
- No past history of PE or DVT

V/Q, ventilation/perfusion; PE, pulmonary embolism; DVT, deep vein thrombosis.
of a false-positive result is at its lowest, it may be adequate to rule out PE if the patient is low risk and the result is normal. Patients who are otherwise low risk should not be automatically assumed to have a high pretest probability just because they are pregnant.

**TREATMENT**

The defining characteristic of the emergency medicine physician is simultaneous treatment and evaluation. Oxygen should be given to patients suspected of having PE. Correction of local hypoxemia assists in decreasing reflexive vasoconstriction in the pulmonary vasculature. Patients who are thought to be at high risk for PE and have a high pretest probability should be considered candidates for empiric treatment with anticoagulation while awaiting the results of tests, provided that they have no contraindications. Low-molecular-weight heparin (LMWH) has become standard therapy despite being more costly than unfractionated heparin. It has benefit in achieving appropriate anticoagulation rapidly without the need to monitor coagulation levels, and it is also associated with a less likelihood of heparin-induced thrombocytopenia with thrombosis. Some studies have suggested that LMWH may have somewhat higher efficacy in terms of time to thrombus resolution and recurrence in patients with DVT. Unfractionated heparin is still a safe and effective treatment and may be especially useful if a shorter term of anticoagulation with the ability to rapidly cease anticoagulation is desired. Unfractionated heparin and LMWH do not act to break down existing thrombus but rather act to decrease thrombus propagation and extension. Endogenous mechanisms of antithrombin and plasmin activation are responsible for gradually effecting thrombus breakdown. The dose of enoxaparin, the most commonly used LMWH, is 1 mg/kg subcutaneously every 12 hours. The dose of unfractionated heparin is typically a 80-U/kg bolus intravenously and then an 18-U/kg/hr intravenous infusion.

**RISK STRATIFICATION**

It is critical to assess the likelihood for further deterioration. Figure 70.1 demonstrates the increase in mortality that occurs gradually with right heart strain and then more steeply with shock. It is possible to gather data in the ED to estimate the likelihood of right heart strain and early shock. The ECG is the starting point, and the presence of T-wave inversion in leads V1 to V4, incomplete or complete right bundle branch block, an S wave in lead I, a Q wave in lead III, and an inverted T wave in lead III may all be evidence of right heart strain. Pulse oximetry is an important predictor of 30-day mortality in normotensive ED patients with PE when less than 95% on room air. Other means of risk stratification include brain natriuretic peptide (BNP) and troponin blood testing. Though not specific for PE and not helpful in establishing the diagnosis, these factors are being seen in emerging studies to predict a more complicated course both in the hospital and several months later. The most accepted means of risk stratification is the echocardiogram. Though often not available on an emergency basis in many EDs, it is a rapid means of identifying right heart strain (Box 70.3).

**TREATMENT OF PATIENTS WITH CONFIRMED PULMONARY EMBOLISM AND SHOCK**

In a practice guideline statement the American College of Emergency Physicians recommended fibrinolytic therapy for hemodynamically unstable patients with confirmed PE as a class B recommendation. (Class B represents a moderate level of certainty.) Despite controversy over the use of thrombolysis and mortality in patients with PE and shock, in selected samples it seems clear that fibrinolytic therapy has been associated with improved perfusion and better right heart function. Catheter-based techniques of thrombus fragmentation, as well as surgical embolectomy, are alternatives to pharmacologic fibrinolysis. These techniques are unlikely to be available outside dedicated interventional radiology and cardiovascular surgery centers and are highly operator dependent. No evidence has shown that they are superior to pharmacologic approaches.

**BOX 70.3 Signs of Severe Pulmonary Embolism on Echocardiography**

- Right heart dysfunction
- RV hypokinesis
- RV dilatation
- Tricuspid regurgitation
- Elevated pulmonary artery pressure
- Impediments to LV output
- Septal shift
- Decreased LV filling

*LV, Left ventricular; RV, right ventricular.*
When the use of fibrinolytics has been studied in patients without overt shock but with right ventricular dysfunction, they have been associated with decreased need to escalate therapy with vasopressors, as well as reduced rates of intubation or additional thrombolytic treatment. The Food and Drug Administration–approved on-label use of fibrinolytic therapy for PE is alteplase, 15 mg as an intravenous bolus and then 85 mg intravenously over a 2-hour period (heparin infusion should be stopped during alteplase administration). Other off-label dosing regimens have been described, including a 15-mg bolus with an 85-mg infusion over a 90-minute period, which has been used in the near-arrest setting. In conclusion, it is accepted that fibrinolytic therapy is appropriate in patients with confirmed PE and shock. Identification of PE as a cause of shock can be aided by a stepwise approach to diagnosis with consideration of other causes of shock (see Fig. 70.2). If shock is present and no right heart abnormalities are seen on echocardiography, PE is a very unlikely explanation for the shock.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Most patients with a new diagnosis of acute PE will be admitted to the hospital for initiation of anticoagulation and serial evaluation of oxygen saturation, blood pressure, and overall functional capacity. Patients with minimal cardiopulmonary comorbidity, normal oxygen saturation, and no evidence of hypotension are typically discharged shortly after warfarin anticoagulation is initiated, and trends outside the United States have included outpatient treatment of low-risk PE patients. In either case, patients continue home self-treatment with LMWH for several days until the outpatient international normalized ratio is above 2.0, at which point they may stop taking LMWH and continue warfarin.

Patients with low oxygen saturation (less than 95%), right heart strain on an echocardiogram or ECG, elevated BNP, or elevated troponin should be observed closely for deterioration. The decision for intensive care unit management should be based on the level of specialized care that patients need (Box 70.4).

Patients with a history of previous PE present several challenges. Recurrent PE, defined as an acute clot in a new or different anatomic location, should be treated as acute PE, and if patients are no longer taking anticoagulation agents, they need treatment as stated earlier. In contrast, a persistent or chronic clot is not uncommonly seen in the same areas as previous PE and may look radiographically distinct from acute PE on CT. If patients are appropriately anticoagulated and do not have other indications for admission, they may be discharged from the ED, provided that no other inpatient evaluation for the symptoms is warranted. However, patients with no new clot visualized on CT may be suffering from chronic venous thromboembolic syndrome, a condition in which pulmonary hypertension and chronic vascular changes in the lung can lead to chronic disabling dyspnea and other symptoms that may prompt ED evaluation. Depending on oxygenation and functional status, these patients should be admitted or, if discharged, referred for outpatient echocardiography and pulmonary consultation, but no specific therapy as yet exists for this condition, which may affect 1% to 3% of all patients with PE (Box 70.5).

**BOX 70.4 Indications for Intensive Care Unit Management of Patients with Pulmonary Embolism**

- Shock
- Mental status: acutely decreased and not improving
- Respiratory effort: poor or worsening
- Cardiac ischemia
- Troponin elevation
- Worsening electrocardiographic findings
- Oxygen requirement: high
- Worsening overall clinical course:
  - Pulse increasing
  - Blood pressure decreasing
  - Oxygen saturations decreasing
  - Recurrent syncope

**BOX 70.5 Future Trends in the Diagnosis, Prognosis, Treatment, and Disposition of Patients with Pulmonary Embolism**

- Electronic decision support aids to provide more accurate point-of-care pretest probability
- Effective risk stratification for short- and long-term adverse events
- Improved understanding of thromophilic states
- Outpatient or emergency department observation-based treatment of selected low-risk new patients with pulmonary embolism
- Oral rapid-acting anticoagulation medications as alternatives to warfarin and low-molecular-weight heparin
- Fibrinolytic therapy for patients at high risk for immediate and delayed adverse events

**TIPS AND TRICKS**

The combination of normal oxygen saturation, no known risk factors, and no pulmonary symptoms is very uncommon.

A targeted diagnostic approach should be used rather than a “chest pain work-up” in an attempt to test for every diagnosis possible without regard to the pretest probability or negative consequences of overtesting.

Many of the most threatening alternative diagnoses can initially be assessed with a chest radiograph, electrocardiogram, bedside echocardiogram, and cardiac enzyme testing during the first hour.

Patients who are otherwise at low risk should not be automatically assumed to have a high-risk pretest probability just because they are pregnant.

Patients with a history of pulmonary embolism and no new clot on computed tomography may be suffering from chronic venous thromboembolic syndrome, a condition in which pulmonary hypertension and chronic vascular changes in the lung can lead to chronic disabling dyspnea.
Mortality in patients who have PE without shock is greater than that in those with acute myocardial infarction. Physician gestalt is useful only when the probability of PE is already very low; therefore, patients who meet the PE rule-out criteria but for other reasons are thought to need testing for PE should undergo the standard evaluation. Patients at high risk by pretest probability assessment and have low or indeterminate V/Q scans cannot be assumed to have PE ruled out. Patients with a high pretest probability are candidates for empiric treatment with anticoagulation agents while awaiting test results, provided that they have no contraindications. Unfractionated heparin and LMWH do not act to break down existing thrombus but rather act to decrease thrombus propagation and extension. The ACEP practice guideline recommends fibrinolytics for unstable patients with confirmed PE as a class B recommendation. Patients without overt shock but with right ventricular dysfunction who are treated with fibrinolytics have a lower need for vasopressors and intubation. If shock exists and no right heart abnormalities are seen on echocardiography, PE is a very unlikely explanation for the shock. Patients with low oxygen saturation (less than 95%), right heart strain on echocardiography or electrocardiography, elevated BNP, or elevated troponin should be observed closely.

ACEP, American College of Emergency Physicians; LMWH, low-molecular-weight heparin; PE, pulmonary embolism; V/Q, ventilation-perfusion.

The decision to test for pulmonary embolism should always assume that if screening tests such as the D-dimer blood test are positive, more definitive tests will be undertaken. It is critical to explain this to patients so that they are not surprised and displeased when many of them have a false-positive D-dimer result and need to stay in the emergency department for imaging. In pregnant patients, a detailed discussion with the patient, radiologist, obstetrician, and the patient’s family should occur at the outset even before tests are ordered and should include the probability of disease, the extremely low probability of radiation-associated negative effects, and the potential morbidity with undiagnosed pulmonary embolism.

References can be found on Expert Consult @ www.expertconsult.com.
Deep vein thrombosis (DVT) is a common diagnosis that may be seen in emergency department (ED) patients with minimal to no symptoms or with obvious findings on examination. DVT most typically arises in the lower part of the leg and may exist in combination with or as a precursor to pulmonary embolism (PE). Together, DVT and PE are termed venous thromboembolism (VTE). Understanding VTE as a single disease is useful because risk factors, urgency in establishing a diagnosis, and treatment are similar for both PE and DVT. The annual incidence of DVT has been estimated to be 92 cases per 100,000 persons, and the rate steadily advances with increased age (32/100,000 in persons younger than 55 years, 282/100,000 in those 65 to 74 years of age, and 553/100,000 in those 75 years or older).1

DVT can occur in both young and old patients and may result in both acute and chronic morbidity. It may be acute and life- or limb-threatening (PE, total iliopelvic obstruction) or can lead to chronic and debilitating complications (postphlebitic syndrome, venous stasis and ulceration, recurrent DVT).

Typical DVT risk factors are summarized by the Virchow triad: trauma, stasis, and hypercoagulability. These risk factors are the same as for PE (Table 71.1). However, 25% to 50% of patients with DVT may have no identifiable risk factor known at the time of evaluation.

The timing of development of DVT is difficult to know, but it typically starts with small asymptomatic abnormalities in flow at the level of the endothelium. It may be precipitated by venous valve dysfunction or immobility, both of which decrease the normal function of the venous-muscle pump system for return of blood from the legs.

DVT can also develop in the pelvic veins (typically associated with comorbid pelvic or gynecologic conditions) or upper extremity (typically with venous catheters), but by far most cases of DVT diagnosed in the ED are in the legs.

Understanding the venous anatomy of the leg is crucial for interpreting risk and diagnostic tests. The most obvious and concerning cases of DVT occur in the proximal deep system. In order from distal to proximal, the proximal deep veins are the popliteal, femoral, deep femoral, common femoral, and finally the external iliac. Occasionally, the femoral vein is referred to as the superficial femoral vein, which results in confusion because it is a deep vein and clots there should be treated as DVT. Thrombosis may develop in the distal deep system (the calf), and these veins are the anterior tibial, the posterior tibial, and the peroneal. These are deep veins and thrombosis here is DVT, but management of isolated distal DVT is somewhat less certain than that for proximal DVT. Finally, the superficial venous system of the leg can be subject to thrombosis and superficial thrombophlebitis, but this is managed differently from thrombosis in the deep system. These veins are the lesser and greater saphenous and the perforating veins. This is not DVT, and isolated thrombosis here is not typically treated with systemic anticoagulation.
The morbidity associated with venous thrombosis is not just due to subsequent embolization. Even with anticoagulation there is the possibility of injury to the endothelium and venous valve system, both of which can result in chronic venous stasis and recurrent clots.

**PRESENTING SIGNS AND SYMPTOMS**

Patients can have a variety of symptoms that may include fullness, cramping, achingness, or vague pain in the calf or posterior part of the leg. They may also report swelling. It is important to distinguish between unilateral symptoms, which may be more likely to be due to DVT, and bilateral symptoms, which may be more likely to be a consequence of some other disease process. The exception would be the rare case of obstruction of the inferior vena cava or simultaneous bilateral DVT. Signs on examination may include edema, redness, and tenderness, particularly in the posterior aspect of the calf or the upper part of the leg.

Swelling may be minimal or extensive and involve the entire extremity. It can be challenging to distinguish chronic symptoms of venous stasis from acute DVT based on a single examination. Therefore, a careful history to establish the time course of the findings in the leg is critical, and examination of the past medical record can be highly valuable.

Use of examination alone to determine the presence or absence of DVT is problematic. Classic teaching is that the accuracy of physical examination alone for the diagnosis of DVT is 50%. This is a bit of a generalization, but it is clear that findings may be subtle, patients may not have detectable tenderness or edema early in the course or spectrum of disease.

severity, and some patients may be nearly asymptomatic. The often mentioned, but rarely understood or performed Homan sign—calf pain elicited by passive dorsiflexion of the ankle—is insensitive, nonspecific, and useless.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Many other diseases may be accompanied by pain, swelling, and tenderness of the leg. Box 71.1 presents a differential diagnosis of conditions that should be considered.

Clinicians often have a difficult time distinguishing between cellulitis and DVT. The pain, swelling, erythema, and unilateral nature of cellulitis may be clinically similar to findings in patients with DVT, and the two conditions can even coexist. A break in the skin, fever, or warmth may more strongly suggest cellulitis. However, distinguishing between the two may be impossible without objective testing for DVT.

Compartment syndrome can be manifested as pain and swelling in the leg and is an emergency, time-dependent diagnosis. Extreme pain, exquisite tenderness in the compartment, coolness of the extremity, and in later stages, diminished pulses and decreased sensation may all indicate this diagnosis. It is most common in the context of trauma to the leg from either penetrating, blunt, or fracture mechanisms. If being considered, it must be assessed by measuring compartment pressures and, if appropriate, emergency orthopedic or traumatic surgery consultation. Trauma of this significance can be considered, if compartment pressures are normal, testing for DVT can and should proceed.

Many of the other conditions in the list of differential diagnoses are easier to differentiate from DVT by close attention to the time course and other symptoms as revealed from a careful patient history. Overall edematous conditions are listed (congestive heart failure, renal failure, liver failure), but they are commonly associated with gradual or recurrent episodes of bilateral edema. The possible important exception is a patient with congestive heart failure who has undergone coronary artery bypass grafting with removal of the saphenous vein. These patients may, if asked, report that they always have some asymmetry in their swelling and leg size.

Baker cyst rupture or inflammation is a common cause of pain behind the knee and even in the calf. It may be very painful and can result in redness and swelling. An acute onset associated with bending over or being on flexed knees suggests this diagnosis, but confirmation is often achieved with an ultrasound study that is otherwise negative for DVT.

**DIAGNOSTIC TESTING**

**PRETEST PROBABILITY**

Just like any possible diagnosis in the ED for which further testing is considered, the first step should be an assessment of what the pretest probability of disease is. This can be done easily by using a clinical decision model such as that derived and validated by Wells et al. to stratify patients as low risk or high risk for having DVT (Table 71.2). It has been also advocated by some authors that experienced clinicians may empirically use clinical gestalt to estimate the probability of DVT as low or not low. In either case, documentation on the medical record should clearly indicate the physician’s pretest probability for having DVT and what the supporting evidence for this may be from the history and examination.

ULTRASONOGRAPHY

Venous duplex ultrasonography is noninvasive, not associated with radiation exposure, and accurate in detecting proximal DVT. It has become the first-line imaging test for DVT. When performed by a certified sonographer and interpreted by a radiologist or other credentialed expert, it has a sensitivity and specificity of approximately 95% for proximal thrombosis. Ultrasonography does present some problems, however, including limited availability at night in many institutions, operator variability, occasional difficulty in visualization because of body habitus, and at times interobserver disagreement regarding distal DVT. Nonetheless, it is the imaging test of choice for most ED clinicians, and absence of DVT on ultrasonography should be reassuring that no DVT requiring emergency treatment is present. The question of whether to include visualization of the infrapopliteal veins and the clinical significance of isolated distal DVT are controversial.\(^6\)

Ultrasound Performed by Emergency Department Clinicians

A limited study compared ultrasound of the common femoral and popliteal veins performed by emergency physicians versus formal duplex ultrasound performed by certified ultrasonographers in radiology or vascular departments.\(^7\)-\(^10\) A sensitivity of 89% to 100% and a specificity of 75% to 91.9% were reported. However, the extent of operator training and the specific protocols used have varied widely among published studies.\(^11\) One study prospectively investigated the performance of ED-based ultrasound by a heterogeneous mix of 56 emergency physicians with varied levels of ultrasound experience and found a summary sensitivity of 70%, which is low for the evaluation of a disease with significant potential morbidity.\(^11\) Not surprisingly, sonographers with the most experience had the most accuracy in this study. It remains to be seen what the best method is to train emergency medicine ultrasonographers for evaluation of DVT and what the overall diagnostic performance would be when done outside academic centers or institutions without ultrasound fellowships and dedicated training. In the future this may be a cost-effective and safe option as this modality evolves. Presently, a clearly negative result of a limited scan performed by a properly trained emergency physician suggests the absence of DVT in the proximal leg veins. If the results are positive or equivocal or involve patients with a high probability, confirmatory studies by the radiology or vascular service should be performed.

Additional or Follow-up Ultrasonography

There can be significant confusion and disagreement between the emergency medicine physician consultant and the literature over the need for additional ultrasonographic studies in patients with negative ultrasound findings. Some suggest that if the initial ultrasound visualized only the proximal system, a second ultrasound as an outpatient is needed. However, studies have found this practice to yield a very low rate of disease. A more common and feasible strategy would be to refer patients with equivocal findings in the distal system or those with a high pretest probability of DVT for additional studies done as an outpatient. Integration of the ultrasound results with pretest probability and D-dimer testing as indicated later can limit confusion on this issue.

VENOGRAPHY

Venography has been the historical “gold standard” for the diagnosis of DVT, but as with pulmonary angiography, this invasive and painful test is now rarely performed. Complications include contrast reaction, contrast nephropathy, vascular injury, and the possibility of subsequent DVT in previously nonthrombosed vessels.

Runoff Venography After Chest Computed Tomography for Pulmonary Embolism

When computed tomography (CT) of the chest is performed as part of imaging for possible PE, some institutions also use a delayed imaging protocol that visualizes the pelvis and legs to assess for the presence of DVT. This may add a marginal value of about 2% to the overall sensitivity of this testing strategy. However, many sites do not use this protocol because of radiation exposure, cost, time needed to read the images, and less than optimal interobserver agreement on the venography aspect of the study. In general, this is a hospital- and radiology-specific decision with no conclusive evidence in the literature on its value. CT venography done independent of a PE protocol study is not typically performed because of the alternative nonradiating and noninvasive nature of duplex ultrasonography.

D-DIMER TEST

The D-dimer test is a blood-based assay that uses antibodies to the D-dimer protein to measure the presence or level of circulating D-dimer. D-dimer is a breakdown product of fibrin, and elevated levels are associated with elevated fibrin or clot somewhere in the body. Unfortunately, elevated D-dimer can occur in a variety of conditions other than acute PE and DVT, most notably malignancy, pregnancy (particularly later trimesters), chronic inflammatory conditions, recent surgery, infection, stroke, myocardial infarction, and even advanced age. For many versions of this test, levels below 500 ng/mL are considered negative, but this may vary by laboratory and assay used.

TIPS AND TRICKS

Testing for Deep Vein Thrombosis

Physical examination alone is unreliable for the diagnosis of deep vein thrombosis (DVT), but duplex ultrasonography is noninvasive and the diagnostic imaging method of choice.

In patients deemed unlikely to have DVT by a Wells DVT score of 1 or less or an empiric unstructured estimate of the probability of DVT of less than 10%, DVT may be essentially ruled out by a quantitative negative D-dimer blood test.

In patients with DVT deemed to be likely by a Wells DVT score of 2 or greater or an empiric unstructured estimate of probability of greater than 10%, negative findings on duplex ultrasound should be followed by either a negative D-dimer test or a negative additional ultrasound as an outpatient before the diagnosis is excluded.
Combining of Pretest Probability, D-Dimer Testing, and Duplex Ultrasonography

This integrated strategy has been advocated as a way to optimize the speed of evaluation, cost, need for imaging, and safety. Similar to the risk stratification and D-dimer approach to PE testing, it starts with physician estimation of the probability of disease in a symptomatic ED patient. If DVT is determined to be “unlikely” by the Wells DVT score (1 or less), a D-dimer test that is negative is reassuring to stop ED testing for DVT and consider other diagnoses.¹² If D-dimer is positive, ultrasound is the next step, with results guiding further decision making. One approach for those who are not “DVT unlikely” still uses D-dimer but mandates that all patients, regardless of the D-dimer result, undergo ultrasonography, and D-dimer is then used to guide who needs follow-up in 1 week for an additional ultrasound. This integrated strategy is shown in Figure 71.1.

![Fig. 71.1 Pretest probability–based diagnostic algorithm for the evaluation of potential deep vein thrombosis (DVT) in emergency department patients. LMWH, Low-molecular-weight heparin.](image-url)
### TREATMENT

Subcutaneous injection of low-molecular-weight heparin (LMWH, including enoxaparin, dalteparin, and others) is the standard of care used to treat acute DVT and provide rapid therapeutic anticoagulation until the effects of oral warfarin are sufficient to result in therapeutic anticoagulation (usually 4 to 7 days). The goal of long-term warfarin treatment is to prevent recurrence of DVT or PE, which is achieved by targeting the international normalized ratio (INR) to a level between 2.0 and 3.0 during the treatment period. Therapeutic anticoagulation may also lower the risk for postphlebitic syndrome, in addition to the risk for recurrent VTE.

Unfractionated heparin administered via continuous infusion is used less often now than in the past, but it can be an option if there is a potential need to rapidly stop the effects of anticoagulation at a later time in care. Other than this unique situation, LMWH has become the first choice for anticoagulation in patients with acute VTE, largely because of the ease of administration, its efficiency in achieving anticoagulation, and the potential reduced bleeding. In the initial treatment of DVT, once-daily dosing appears to be as effective and safe as twice-daily dosing, but the frequency may vary with the agent used.

The duration of warfarin treatment may vary by patients. Typically, it is taken for 3 to 6 months. Patients with provoked DVT (from a specific temporary event such as an injury, surgery, or pregnancy) are more likely to have warfarin discontinued at 3 to 6 months than are patients with active cancer or unprovoked idiopathic VTE. Some oncologists and hematologists recommend daily LMWH for oncology patients with VTE rather than transition to warfarin, and some patients with nontemporary risk factors for VTE, such as incurable malignancy, may be maintained on an anticoagulation regimen for life. Both LMWH and warfarin reduce the development of additional thrombosis but do not have a mechanism of action that dissolves or lyses the existing clot. The natural fibrinolytic system accomplishes this task to a varied degree in each individual patient, depending on many factors. Pharmacologically, lysis can be facilitated by use of thrombolytic agents, but at present such treatment is indicated only for extensive limb-threatening thrombosis not amenable to vascular surgery and other rare instances.

Other anticoagulants, such as direct thrombin inhibitors and factor Xa inhibitors, have been developed and are undergoing additional testing in large trials. These anticoagulants have the advantage of rapid time to therapeutic effect and ease of oral dosing and appear to be equally effective as LMWH plus warfarin, but they are not easily reversed and may incur a significant increase in cost relative to warfarin alone.

### DISPOSITION

Most patients with acute DVT who have the ability to self-administer subcutaneous injections of LMWH, continue warfarin anticoagulation as an outpatient, have a means of determining the INR, and have additional follow-up arranged can be discharged from the ED. Of course, if other conditions are thought to be present that mandate inpatient testing or treatment, patients are admitted for inpatient care. Patients who are thought to have concomitant PE based on clinically significant signs or symptoms may require testing for this condition and admission for monitoring of oxygen saturation and the degree of pulmonary symptoms, but pharmacologic treatment remains the same for PE and DVT. The counterintuitive practice pattern whereby patients are typically discharged from the ED with uncomplicated DVT but often admitted for uncomplicated PE is subject to ongoing debate, with some experts advocating for outpatient care of PE in patients who do not have an oxygen requirement and are otherwise at low risk for adverse events. In the absence of randomized trials or large-scale observational data, this debate lingers as an evolving area of potential health services research. In any case, clinicians are not mandated to order pulmonary angiography or chest CT in patients without pulmonary or chest symptoms and should not embark on a quest to find PE in every patient who has DVT. Such a strategy would be costly, expose the patient to radiation and other potential risks such as contrast reaction and nephropathy, and would not change management. Explaining this to patients requires deliberate, clear communication but may be helpful in reducing subsequent anxiety as they learn more about VTE in the outpatient setting. Finally, follow-up must be emphasized as being important. The clinical course of acute DVT is impossible to predict, even with appropriate anticoagulation treatment.

### RED FLAGS

The superficial femoral vein is actually part of the deep venous system, and thrombosis there should be treated as acute deep vein thrombosis (DVT).

Age is a potent risk factor for DVT, as it is for pulmonary embolism. Although advanced age is not part of the Wells prediction model for DVT, it should be considered when estimating the probability for DVT and the need for imaging.

Patients taking warfarin may still have DVT or extension of DVT despite a therapeutic international normalized ratio. Do not “rule out” DVT solely on the basis of the absence of risk factors.

The role of emergency department–based ultrasonography is evolving but is operator dependent, and most protocols examine only portions of the proximal deep venous system. Specific training and experience are needed. Caution may be warranted in formulating treatment decisions based on findings that may not have optimal visualization or that may be equivocal.

### SPECIAL CASES RELATED TO TREATMENT OR DISPOSITION DECISIONS

#### SUPERFICIAL THROMBOPHLEBITIS

Painful inflammation of superficial veins because of thrombus is called superficial thrombophlebitis. Because it is possible for DVT to be present with superficial thrombophlebitis, it is not unreasonable to consider ultrasound evaluation in these...
patients. If deep venous involvement is not present, a thrombus in the superficial vein is not generally thought to pose a threat for significant embolization, but appropriate follow-up and return instructions are needed because in a minority of these patients, DVT or worsening of their superficial disease may eventually occur.

Outpatient treatment of superficial thrombophlebitis usually consists of nonsteroidal antiinflammatory medications, heat, and compression. The pain may persist for weeks, and the condition may recur.

**ISOLATED CALF DEEP VEIN THROMBOSIS**

Treatment of isolated calf DVT with anticoagulants is controversial. Advocates of treatment cite the not-insignificant risk for proximal propagation and potential subsequent PE. Opponents argue that isolated calf DVT is less likely to be associated with clinically significant PE. Opponents argue that isolated calf DVT is less likely to be associated with clinically significant PE. A period of several days to a week of outpatient treatment with 325 mg of aspirin daily and ultrasound repeated within 1 week may be an option in these patients if discussed with the patient and primary physician.

**PHLEGMASIA CERULEA DOLENS**

Extensive iliofemoral thrombosis may rarely produce an enlarged, doughy, painful blue leg, a condition called phlegmasia cerulea dolens. Greatly increased hydrostatic pressure from occluded venous flow results in impressive edema. The edema elevates tissue pressure, which ultimately impedes arterial flow and produces ischemic conditions and cyanosis. If the obstruction is not relieved, venous gangrene may ensue, with loss of limb and high mortality. Unfractionated heparin should be started, and because the patient’s intravascular volume is depleted as a result of third spacing, fluid resuscitation should also be administered. This is a time-dependent emergency, and if available, vascular surgery should be consulted for consideration of thrombectomy. Alternatively, systemic thrombolytic therapy with tissue plasminogen activator is a potential strategy if vascular surgery is unavailable or operative risks are deemed to be too high.

**POSTPHLEBITIC SYNDROME**

Venous thrombosis may eventually result in chronic valvular incompetence through inflammatory damage, partial recanalization with the presence of residual clot, or simple vessel distention producing loss of coaptation of valves. With loss of normal valve function, blood return from the lower extremity depends on higher venous pressure. This pressure distends the veins and becomes painful. Depending on the extent of valvular damage, the discomfort may be mild or highly disabling. Patients commonly suffer from some degree of chronic edema and skin changes, which can progress to ulceration. Patients with severe forms of this disorder may not be able to stand or walk for significant periods and are unable to exercise. Such disability may be career changing and can occur in young, otherwise healthy individuals.

Lower Extremity Venous Ultrasonography

James Q. Hwang and Vicki E. Noble

KEY POINTS

- Lower extremity ultrasound is the primary modality used to diagnose or exclude deep vein thrombosis (DVT).
- Clinician-performed bedside ultrasound can be accurate in detecting DVT when compared with radiology-performed examination.
- Two-point compression lower extremity ultrasound is a simplified approach that consists of compression of the common femoral vessels in the groin and the popliteal vessels in the popliteal fossa.
- Compressibility of veins via gray-scale B-mode ultrasound is the most important criterion for assessing DVT.
- Current practice guidelines recommend that proximal lower extremity ultrasound be repeated in 5 to 7 days after an initial negative two-point compression result to rule out propagation of unseen distal DVT.

EPIDEMIOLOGY

About 250,000 cases of deep vein thrombosis (DVT) are diagnosed each year. Failure to recognize and appropriately manage DVT can increase risk for the development of post-thrombotic syndrome (disabling leg symptoms caused by venous reflux or ulceration) or pulmonary embolism (PE).1-4

DVT may develop in the lower or upper extremities. Although up to 18% are located in the upper extremities,5 the majority arise from the lower extremities. In the lower extremities, DVT is referred to as proximal when it is found in the popliteal veins or higher and as distal when it is located in the calf.

PERSPECTIVE

Unfortunately, the diagnosis of DVT cannot be made on clinical signs and symptoms alone. The location of swelling and pain does not correlate with the location or extent of the clot, and symptoms localized to the calf may have an etiology in more proximal veins.6 Clinical signs have been analyzed statistically and found to be of little value in reliably determining the presence or absence of DVT.7 The differential diagnosis for leg pain and swelling includes lymphedema, chronic venous insufficiency, infection (cellulitis), aneurysm, pseudoaneurysm, Baker cyst, and other musculoskeletal causes. Diagnosis of DVT depends on the clinician’s pretest probability assessment and a combination of several noninvasive diagnostic tools (lower extremity ultrasound, D-dimer, or both). The exact diagnostic path or algorithm pursued depends somewhat on local availability and expertise. When available, lower extremity ultrasound is the primary modality used to diagnose or exclude DVT. The lower extremity ultrasound may be a proximal lower extremity examination, a whole-leg examination, or an abbreviated, two-point compression examination. If proximal lower extremity ultrasound is performed, current practice guidelines recommend that ultrasound of the proximal veins be repeated 5 to 7 days after an initial negative result to safely exclude clinically suspected DVT.8,9 This recommendation stems from the observation that up to 20% of cases of distal DVT may propagate into the proximal veins.10,11

A systematic review and metaanalysis published in 2010 found that after a negative whole-leg study, anticoagulation may be withheld safely without the need for a repeated ultrasound examination.12

Despite the numerous benefits of lower extremity sonography, many emergency providers continue to be unable to obtain lower extremity ultrasound after hours, on weekends, and on holidays. Clinician-performed two-point compression lower extremity ultrasound is now considered an appropriate method for assessing lower extremity DVT in the emergency department (ED) and is one of the 11 core emergency ultrasound applications.13,14 Emergency providers who perform two-point compression lower extremity sonography have demonstrated scan times of less than 4 minutes per patient and time savings of more than 2 hours in terms of time to patient disposition.15,16 When ultrasound is not available, providers may be forced to administer low-molecular-weight heparin and either keep the patient in the ED overnight or coordinate an outpatient study for the patient the following day. Although the risk for bleeding in these situations is low, boarding the patient in the ED or relying on patient-initiated follow-up is less than ideal. Given ever-increasing patient volumes and ED crowding, the value of clinician-performed two-point compression lower extremity ultrasound cannot be overstated.
EVIDENCE-BASED REVIEW

Radiology-performed lower extremity duplex ultrasound has reported sensitivities of 91% to 96% and specificities of 98% to 100%.17,18 Multiple studies have demonstrated that clinician-performed two-point compression bedside ultrasound can be accurate in detecting DVT when compared with radiology-performed examinations.19,22 In a systematic review, Burnside et al. found an overall sensitivity of 95% and specificity of 96% for detection of lower extremity DVT by emergency physician–performed ultrasound.19 The authors caution that the six studies included in their analysis were limited by small sample size and by emergency physicians with high levels of ultrasonographic expertise, thus leaving their estimates at risk for being overly optimistic. A prospective study by Kline et al. in the same year assessed a more diverse range of clinician sonographers with more limited training in ultrasonography and found a sensitivity of 70% and specificity of 89%.20 They concluded that ultrasound performed by providers with limited training in compression ultrasonography of the lower extremity had intermediate diagnostic accuracy that may be improved by pretest probability assessment. A more recent prospective study by Crisp et al. included a large, heterogeneous group of emergency providers with variable levels of ultrasonographic experience but found the test results to be similar to those from the Burnside review with a sensitivity of 100% and specificity of 99%.21

It is important to note that clinician-performed lower extremity sonography focuses on compressibility and typically does not include color flow Doppler or pulsed wave spectral Doppler beyond its use to localize or distinguish between vessels. Compressibility of veins with gray-scale B-mode ultrasound is the most important criterion and is widely accepted as being highly accurate.1 Color flow Doppler and pulsed wave spectral Doppler provide additional information and may be particularly useful when uncertainty exists or when assessing for pelvic DVT. Even though Doppler imaging has utility, it can be limited by the following: nonocclusive thrombus, the presence of collateral flow, and sonographer skill. Some studies have found that Doppler adds little to the information obtained by compression ultrasound for the detection of proximal DVT.22 In a prospective study by Biondetti et al., vein compressibility alone was compared with contrast-enhanced venography and found to have an overall sensitivity of 87% and a specificity of 100%.23 Because six of the seven false-negative examinations resulted from isolated distal DVT, the sensitivity of compression-only ultrasound for detecting proximal DVT was noted to be 98%. It is reasonable that clinician-performed lower extremity ultrasound studies consist only of compression.

TWO-POINT COMPRESSION VERSUS WHOLE-LEG COLOR DUPLEX ULTRASOUND

Two-point compression lower extremity ultrasound is a simplified approach that consists of compression of the common femoral vessels in the groin and the popliteal vessels in the popliteal fossa. The concept behind this abbreviated approach stems from the idea that clot usually involves multiple or whole venous segments. Several studies have shown that few cases of proximal DVT occur without involving either the common femoral vein (CFV) or the popliteal vein (PV), or both, and that isolated thrombus in the superficial femoral vein (SFV) is rare.24-27 In a study of limited compression ultrasound in patients with symptomatic DVT, Pezzullo et al. found a 54% reduction in examination time (9.7 minutes) while still maintaining high accuracy and patient safety.20 To the contrary, Frederick et al. prospectively studied 721 symptomatic patients and determined after 755 examinations that DVT limited to a single vein occurs with sufficient frequency that the lower extremity ultrasound cannot be abbreviated without resultant loss of diagnostic accuracy.28 To that end, in a retrospective study of 2704 lower extremity ultrasound examinations, Maki et al. found that acute DVT was isolated to the SFV in 22.3% of patients with DVT.29 They concluded that abbreviated imaging studies that evaluate only the CFV and PV could fail to detect up to 20% of proximal DVT and recommended interrogation of the SFV. The question of whether two-point compression can be performed in place of full-length examination remains controversial. In clinical situations in which radiology-performed, whole-leg sonography is not available, there is little controversy; clinicians should proceed with performing two-point compression lower extremity ultrasound. One solution to the vexing problem of missed SFV clots is to perform “two-region” compression ultrasound—that is, perform compression in the groin region from the greater saphenous junction through the bifurcation of the superficial and deep femoral veins and perform compression in the popliteal region from the PV to the trifurcation of the distal calf veins. This “two-region” approach has not been studied as a specific technique, although previous research would seem to support it as a compromise approach.

The value of whole-leg color duplex ultrasound is dependent on the significance of identifying distal DVT. The clinical relevance plus need to treat distal DVT is a controversial topic that continues to be debated. Proponents of full-length lower extremity examination point to a randomized trial by Lagerstedt et al. in which the usefulness of long-term anticoagulation (for 3 months) was assessed in patients with distal DVT. The authors found that those who did not receive long-term anticoagulation therapy had a significantly higher recurrence rate than those who did (8 of 28 patients versus 0 of 23 patients; \( P < .01 \)).30 This study suggests that calf vein thrombi are important, should be sought in symptomatic patients, and when found, should be treated with long-term anticoagulation. Although the American College of Chest Physicians is in agreement with these findings,31 there is no universally accepted consensus on the management of distal DVT.32 Proponents of full-length examination often point to literature in which a proximal progression rate of up to 20% has been observed.30,31 Righini et al. contend that there is considerable uncertainty over the natural history of distal DVT and, in particular, over the rate of extension to proximal veins.33 The authors argue that if identifying and treating distal DVT do not improve patient outcomes, whole-leg color duplex ultrasound is of less clinical utility. Previous trials have demonstrated that it is safe to withhold anticoagulation in patients with suspected venous thrombosis and negative serial proximal ultrasound results even though some patients have calf vein thrombi.34 In a more recent, prospective, randomized multicenter study, Bernardi et al. compared serial two-point ultrasonography plus D-dimer testing with whole-leg color-coded Doppler ultrasonography for diagnosing suspected symptomatic DVT.35 Although the two-point protocol missed
65 cases of isolated calf DVT, the long-term outcomes for the two groups were similar, thus suggesting that searching for distal clots may be unnecessary.

**ONE LEG VERSUS BOTH LEGS**

The question of whether lower extremity ultrasound examination should include only the symptomatic extremity or both lower extremities is a controversial topic. Proponents of scanning both legs point to literature demonstrating that unsuspected contralateral DVT and bilateral DVT are not uncommon and occur in up to 30% of cases. By interrogating both legs, a baseline study for future comparison can be obtained that may help differentiate acute from chronic venous thrombosis. Opponents of the bilateral lower extremity approach point to literature that describes the likelihood of finding clot solely in the asymptomatic leg to be as low as 0% to 1%. A retrospective study by Strothman et al. found that unilateral scanning would decrease examination times by 21% and could potentially increase total reimbursement for symptomatic venous scans by 9% when compared with routine bilateral duplex scanning. Supporters of single-leg studies note that treatment of DVT is typically the same regardless of whether DVT is found to be unilateral or bilateral. Because treatment with systemic anticoagulation is not altered and the potential indication (assuming contralateral DVT and bilateral DVT are not uncommon), but spectral Doppler, when performed, must at a minimum include spectral waveforms from both lower extremities.

**HOW TO SCAN**

Lower extremity ultrasound is performed with the ultrasound machine positioned on the right side of the patient. Most ultrasound machines have different settings, and if available, the vascular or venous lower extremity setting should be selected. Room lighting should be decreased as much as possible to reduce the amount of gain required and help optimize the image. Typically, a linear probe with a frequency of 8 to 10 MHz is used (Fig. 72.1). For larger patients or those with significant edema, a probe with a lower frequency of 5 to 8 MHz may be used. Transducers with a curved footprint may make compression and assessment of vessel collapse more challenging. The probe should be held with the transducer marker pointing toward the patient’s right side or, in an equivalent manner, pointing toward the sonographer’s left side. The patient is positioned in the supine position with the head of the bed elevated 30 to 45 degrees, or alternatively, the head of the bed may be elevated in the reverse Trendelenburg position. Placing the patient in this position distends the lower extremity vessels and allows easier visualization and assessment. Color flow Doppler and pulsed wave spectral Doppler may be used to help distinguish or localize vessels when visualization through soft tissue is poor. The depth and focal zones should be adjusted accordingly to optimize the image.

Compressibility is determined by applying direct pressure over the vein with the probe and assessing for coaptation of the vessel walls. It is important to note that firm pressure is often required and that the appropriate amount of downward pressure is typically achieved when the walls of the adjacent artery begin to deform. Compressibility is normal when coaptation of the vessel walls and complete obliteration of the intravascular space are seen. Anything short of this is concerning for DVT. With the amount of pressure required, some have questioned whether lower extremity ultrasound could potentially dislodge a thrombus and result in PE. Only one case report of PE resulting from compression sonography has been published. In general, compression sonography is regarded as safe, and gentle compression is advised. In situations in which thrombus can be directly visualized or is noted to be free floating, compression is not generally indicated. Another key point is the importance of applying pressure evenly and not at an angle; otherwise, the probe may roll off the vessel. A frequent initial challenge of performing lower extremity ultrasound is keeping the vessel in the middle of the viewing screen as pressure is applied. The probe is marched one probe width or approximately 1 to 2 cm at a time down the lower extremity. Acute DVT is diagnosed when the vein is found to be noncompressible. In some instances, thrombus may be directly visualized, but it is important to note that acute DVT tends to be less echogenic than chronic thrombus (Figs. 72.2 to 72.6). Acute DVT may also expand the vessel lumen or appear as a color void on color flow Doppler (Fig. 72.7).

Compression sonography of the lower extremity begins just below the inguinal ligament, where the CFV is identified medially to the common femoral artery (Figs. 72.8 to 72.10). Within a few centimeters below the inguinal ligament, the most proximal branch of the CFV may be seen—the greater saphenous vein (GSV). The GSV runs medial and superficial as the probe is moved caudal away from the inguinal ligament (Figs. 72.11 and 72.12). Compression of the proximal GSV at its junction with the CFV is important because thrombus in this location is considered DVT and requires treatment. As the probe is marched caudal, the CFV then divides into the SFV...

and the deep femoral vein (DFV). It is important to recognize that the SFV is part of the deep venous system and not a superficial vein despite its name. There is considerable duplication of the lower extremity venous system, with multiple femoral veins occurring at a frequency of up to 20% to 30%. Compression sonography of the first few centimeters of the SFV and DFV should be performed, and once completed, the scan then proceeds down behind the knee in the popliteal fossa. To obtain access to the popliteal fossa, the
Fig. 72.13 The common femoral vein (CFV) divides into the SFV and the DFV.

Fig. 72.14 The common femoral artery divides into the superficial femoral artery (SFA) and the deep femoral artery (DFA). The common femoral vein divides into the superficial femoral vein (SFV) and the deep femoral vein (DFV).

Fig. 72.15 The popliteal vein divides into the anterior tibial vein, peroneal vein, and posterior tibial vein.

Fig. 72.16 The popliteal vein (PV) is more posterior than the popliteal artery (PA), and because the probe is placed posteriorly in the popliteal fossa, the PV appears more superficial on the viewing screen.

The lower extremity is flexed and externally rotated. Alternatively, the patient may be positioned in either a decubitus position with the study side up or in a prone position with the knee flexed 20 to 30 degrees. The PV is more posterior than the popliteal artery. Because the probe is placed posteriorly in the popliteal fossa, the PV appears more superficial on the viewing screen (i.e., at the top in the near field) (Figs. 72.15 to 72.17).

The probe is placed behind the knee, high in the popliteal fossa, and compression is performed. The probe is then marched caudad along the PV until it trifurcates into the anterior tibial vein, posterior tibial vein, and peroneal vein (Fig. 72.18). It is important to scan the most proximal portions of these calf veins because thrombus in any of these locations is considered DVT and warrants anticoagulation. Although the
venous system is relatively straightforward in the proximal end of the lower extremity, there is considerable variability below the popliteal fossa and in the calf. As per the ACR-AIUM practice guidelines, interrogation of the calf veins is not required. Even with the most careful and detailed examination of the calf veins it can be difficult to be certain that all of the possibly duplicated veins are free of thrombus.

**HOW TO INCORPORATE INTO PRACTICE**

Clinician-performed lower extremity ultrasound can be performed in any patient with suspected DVT. As stated previously, the diagnosis of DVT depends on pretest probability assessment and a combination of several noninvasive diagnostic tools. In a certain subset of patients, D-dimer combined with clinical assessment may be used to eliminate or safely reduce the number of patients needing further noninvasive testing. Even with the use of such algorithms, D-dimer testing can exclude only less than half of patients with suspected DVT. With focused education and training, emergency providers may perform lower extremity ultrasound accurately and safely integrate bedside sonography into their specific DVT evaluation algorithms. Providers must remember that current practice guidelines recommend that proximal lower extremity ultrasound be repeated in 5 to 7 days after an initial negative result. Emergency providers should recognize that patient follow-up can be an issue and limitation. In a prospective observational study assessing patient follow-up after negative lower extremity bedside ultrasound, McIlrath et al. found that only 28% of patients obtained a follow-up ultrasound examination to rule out propagation of unseen distal DVT.

Traumatic Brain Injury (Adult)

Tomer Begaz

**KEY POINTS**

- Emergency treatment of traumatic brain injury is aimed at rapidly identifying surgically correctable lesions and preventing secondary insults such as hypoxemia and hypotension.
- Triage to a neurosurgical trauma center is recommended for patients with intracerebral hemorrhage or persistent altered mental status.
- Early computed tomography is used to identify intracranial hemorrhage in patients with a significant mechanism of injury, history of altered mental status, or risk factors such as anticoagulant therapy.
- Osmotic agents such as mannitol or hypertonic saline are important first-line therapies for patients with elevated intracranial pressure.
- Hyperventilation should be avoided except as a temporizing measure in patients with impending herniation.
- A significant proportion of patients with mild head injury will have persistent postconcussive symptoms. All head-injured patients should be counseled about this possibility and be given appropriate outpatient referral.
- Athletes suffering from concussion should return to play only after completing a supervised stepwise rehabilitation program.

**EPIDEMIOLOGY**

Traumatic brain injury (TBI) is one of the leading causes of morbidity and mortality worldwide, with more than 100,000 deaths annually in the United States alone. In addition, an estimated 2 million individuals suffer permanent, life-altering disabilities each year from these injuries. TBI has resulted in a greater number of years of productive life lost than either heart disease or stroke. The most common causes of TBI are falls, motor vehicle collisions, and assault.

**PATHOPHYSIOLOGY**

Hemorrhage or edema following TBI leads to rapid increases in intracranial pressure (ICP). Initially, cerebrospinal fluid (CSF) can be shunted out of the skull via the ventricles and cisterns. However, after severe TBI, this capacity is quickly overcome, and a rapid rise in ICP with compromised cerebral blood flow and cerebral ischemia ensues. Ultimately, the brain tissue itself may be forced downward across the rigid tentorium or out of the base of the skull itself, thereby resulting in a herniation syndrome and rapid death. Systemic hypoxia and hypotension occur with high frequency in patients with TBI and are associated with increased mortality (Fig. 73.1).

**PRESENTING SIGNS AND SYMPTOMS**

**GLASGOW COMA SCALE SCORE**

An altered level of consciousness in the setting of trauma is the primary indicator of TBI requiring an advanced level of care. The Glasgow Coma Scale (GCS) score is the method most commonly used to quantify level of consciousness. In particular, changes in the GCS score over time are highly predictive of outcome, thus mandating repeated assessments both in the field and in the emergency department (ED).

**CLINICAL FINDINGS**

In addition to the GCS score, the initial clinical examination should include assessment for pupil reactivity and symmetry, focal sensorimotor deficits, and cerebellar abnormalities. A thorough cranial examination should be performed to identify external evidence of trauma, potential skull fracture, or evidence of basilar skull fracture. Signs of basilar skull fracture include periorbital (raccoon eyes) or retroauricular (Battle sign) ecchymosis, hemotympanum, and CSF otorrhea and rhinorrhea. In the setting of TBI, any fluid leaking from the nose or ears should be suspected to be CSF. Because of the high coincidence of cervical spine fractures in the setting of severe TBI, the cervical spine should be examined carefully and imaged liberally as clinically indicated.

Historical features that should raise suspicion for serious intracranial injury include a history of loss of consciousness or posttraumatic amnesia, severe headache, vomiting, and confusion. Patients taking anticoagulant medications and those with bleeding disorders are at higher risk for intracranial hemorrhage and should be imaged liberally.
DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

IMAGING

Non–contrast-enhanced computed tomography (CT) is the initial imaging study of choice in the evaluation of patients with TBI. Plain radiographs are neither sensitive nor specific in identifying intracranial lesions or skull fracture and are therefore not recommended as a diagnostic study. CT has excellent sensitivity in detecting the presence of intracranial hemorrhage, a mass effect such as ventricular compression or midline shift, and the presence of significant cerebral edema. CT also has the advantage of being widely available and rapid. See Box 73.1 for examples of CT findings in patients with TBI.

Other modalities used to diagnose TBI include magnetic resonance imaging (MRI), functional imaging, brain acoustic monitoring, and bispectral electroencephalography. MRI is superior to CT in identifying cerebral edema and diffuse axonal injury. In addition, analysis sequences allow sensitive detection of acute hemorrhage, particularly in the brainstem and posterior fossa, where CT is less sensitive. However, application of MRI in the management of TBI has been limited because of the lack of uniform availability, the increased time needed for administration and patient isolation during the procedure, and the added challenges of resuscitation and ventilator management within the strong magnetic field. For this reason, MRI is used more commonly in the subacute or chronic phases or in patients whose signs and symptoms are not well explained by the findings on CT. Functional imaging with positron emission tomography, single-photon emission CT, xenon-enhanced CT, and MRI-based imaging may also be useful later in a patient’s course to assess cerebral blood flow and oxygenation, which has prognostic value in predicting functional outcomes but is unlikely to be useful in the acute resuscitation and management of patients with TBI in the ED. Finally, newer modalities such as brain acoustic monitoring and bispectral electroencephalography appear to be useful in the detection of TBI because of prognostic ability rivaling that of CT and the ability to provide continuous data. Future investigations should focus on the utility of these modalities in the ED setting.

BOX 73.1 Findings on Computed Tomography in Individuals with Traumatic Brain Injury

Acute hemorrhage appears hyperdense on computed tomography (CT) scans, with the shape and location of hemorrhage suggesting the underlying pathology. Epidural hematomas are classically lentiform (lens shaped) because of their relationship to arterial injury, with the higher pressure compressing the brain parenchyma (Fig. 73.2). Subdural hematomas are more commonly crescent shaped, with blood torn veins tracking along the surface of the brain beneath the dura mater (Fig. 73.3). Intraparenchymal hemorrhage can exist as a discrete hematoma or as multiple smaller foci throughout a contused area of brain (Fig. 73.4). In addition to focal areas of hemorrhage, cerebral contusions typically involve cerebral edema, which may progress markedly over a period of several days. Skull fractures may be seen on plain radiographs, but more important is the potential for injury to the underlying brain parenchyma or the existence of intracranial hemorrhage (Fig. 73.5). Subarachnoid hemorrhage appears as hyperdensities within the ventricles, along the falx and tentorium, and around the circle of Willis (Fig. 73.6). One of the most elusive diagnoses is diffuse axonal injury, in which the findings on CT are often much less impressive than the degree of obtundation. Small, punctate hemorrhages along the gray-white interface at the cortical periphery suggest this diagnosis, although the initial scan may be completely normal.

TREATMENT

GENERAL

The approach to patients with suspected TBI is directed toward reversal of physiologic derangements and avoidance of secondary insults, early triage to a facility with appropriate resources, and expedited neurosurgical care.
CHAPTER 73  TRAUMATIC BRAIN INJURY (ADULT)

Fig. 73.2  A, Normal head computed tomography (CT) scan at the same level as B. B, Bilateral epidural hematomas on a head CT scan.

Fig. 73.3  A, Normal head computed tomography (CT) scan at the same level as B. B, Large subdural hematoma with a midline shift and compression of the ventricles on a head CT scan.

PREHOSPITAL MANAGEMENT

Half of all patients who die of TBI do so within the first few hours after their injury.

Prehospital assessment of patients with TBI should include rapid airway evaluation, continuous pulse oxygen saturation monitoring, frequent measurement of blood pressure, determination of GCS scores, and pupillary evaluation. Prehospital intubation should be avoided in patients who are spontaneously breathing and maintaining greater than 90% oxygen saturation. Prehospital airway management may be necessary in patients with a GCS score lower than 9 or those unable to maintain oxygen saturation greater than 90% with supplemental oxygen. If prehospital endotracheal intubation is performed, confirmation of placement should be done with auscultation and end-tidal capnography. Even mild hyperventilation should be avoided in all cases with the exception of patients who have evidence of herniation or acute neurologic deterioration. Hypotension should be treated with isotonic fluids, although protocols involving prehospital hypertonic saline administration are reasonable for patients with GCS scores lower than 9. Rapid transport is a priority, ideally to a facility with immediately available imaging and neurosurgical care.
AIRWAY AND BREATHING

Trauma data registries have shown increased mortality in TBI patients with hypoxemia. This association has led to an aggressive approach to airway management in patients with severe TBI, including oxygen supplementation and early intubation. All patients with TBI should undergo pulse oximetry monitoring and administration of supplemental oxygen to correct the hypoxemia (Pao₂ < 60 mm Hg or oxygen saturation < 90%).

In patients with severe TBI, endotracheal intubation is critical. Indications for endotracheal intubation include a GCS score lower than 9, airway protection when airway protective reflexes are in question, hypoxia refractory to supplementary oxygen, and agitated or combative patients who cannot comply with a rapid and thorough assessment, including CT.

Rapid-sequence intubation (RSI) is the recommended strategy for securing the airway in patients with TBI because of its ability to produce optimal intubation conditions and minimize the adverse effects of laryngoscopy on the injured brain. The most serious risk associated with RSI is the potential for apnea and hypoxia during paralysis. Aggressive preoxygenation and early use of adjunctive airway measures can minimize hypoxic insults.

Patients with TBI may be sensitive to the increases in ICP associated with RSI, and some experts recommend neuroprotective adjuncts to traditional RSI medications. Preadministration of lidocaine at a dose of 1.5 to 2 mg/kg may blunt the rise in ICP associated with laryngoscopy and intubation. Coadministration of 2.5 to 3 mcg/kg of fentanyl with the induction agent may prevent the tachycardia and hypertension.
of therapy is volume replacement with intravenous fluids and blood products. Albumin and nonprotein colloids have no role in the initial resuscitation of patients with TBI.\textsuperscript{8} Hypertonic saline solutions appear to have osmotic properties that may lower ICP and decrease cerebral edema. However, outcome data have been disappointing,\textsuperscript{10} and at this time the initial resuscitation fluid of choice remains standard crystalloid (lactated Ringer or 0.9% saline solution).

**AVOIDING CEREBRAL HERNIATION**

The development of unilateral papillary dilation, hemiparesis, or deterioration in the level of consciousness is very concerning for the devastating complication of cerebral herniation. Heroic measures are in order. Aside from definitive neurosurgical management, the emergency physician should perform two interventions in this setting: hyperosmolar therapy and hyperventilation.

Patients with cerebral herniation should receive mannitol, 0.25 to 1 g/kg in bolus form, repeated every 4 to 6 hours.\textsuperscript{3,11} Mannitol is an osmotic diuretic that can decrease brain edema, reduce blood viscosity, and cause a transient increase in circulating volume that improves cerebral blood flow and oxygenation. Hypertonic saline at concentrations of 7.2% to 23.4% has been studied as an alternative or adjunct to mannitol with favorable results. This is a promising therapy that has been beneficial in multiple small studies,\textsuperscript{12-15} but at the time of this writing, evidence has not yet reached the level to change practice guidelines, and we therefore still recommend mannitol as the first-line hyperosmolar therapy.

Hyperventilation temporarily lowers ICP as a result of cerebral vasoconstriction. As stated earlier, the decrease in ICP seen with hyperventilation comes at the price of an even greater compromise in cerebral blood flow, which ultimately results in cerebral ischemia. Impending herniation is the one clinical setting in which transient hyperventilation, to a \( \text{Paco}_2 \) value of 30 to 35 mm Hg, should be initiated as a temporizing measure until hyperosmolar therapy takes effect or surgical decompression can be performed.

**SEIZURE PROPHYLAXIS**

Seizures in patients with TBI have a constellation of effects, including elevated ICP, hypoxia, hypercapnia, and massive release of excitatory neurotransmitters, all of which result in secondary insults to an already injured brain. Seizures should be treated immediately with benzodiazepines. There is no evidence that early seizure prophylaxis decreases the likelihood that a delayed seizure disorder will develop, but prophylaxis does decrease the likelihood of early seizures (within the first 7 days after injury). The decision to empirically administer seizure prophylaxis should weigh the likelihood of seizures against the possible side effects of medication. There is currently no consensus regarding which patients should receive prophylaxis, but it is reasonable to consider administration in high-risk patients. Patients at high risk for seizures include those with a GCS score lower than 10, cerebral contusion or hematoma, depressed skull fracture, and penetrating injury.\textsuperscript{3} The first-line agent for seizure prophylaxis is phenytoin.

---

**CHAPTER 73 TRAUMATIC BRAIN INJURY (ADULT)**

**BOX 73.2 Example of a Neuroprotective Induction Strategy for Individuals with Traumatic Brain Injury**

1. Preoxygenate with 100% \( \text{O}_2 \).
2. Administer lidocaine, 1.5 to 2 mg/kg.
3. Administer a defasciculation dose of a nondepolarizing neuromuscular blocking agent (e.g., rocuronium, 0.1 mg/kg, or pancuronium, 10 mcg/kg).
4. Administer fentanyl, 2.5 to 3 mcg/kg.
5. Induce with etomidate, 0.3 mg/kg.
6. Paralyze with succinylcholine, 1.5 to 2 mg/kg.

---

**CIRCULATION**

Systemic hypotension has been associated with increased mortality in studies of TBI. Although the normal brain can maintain cerebral blood flow despite a range of mean arterial pressure levels, this ability appears to break down following TBI. In addition, intracranial hypertension requires higher mean arterial pressure to maintain adequate cerebral perfusion pressure. Every effort should be made to avoid hypotension in TBI patients and maintain systolic blood pressure lower than 90 mm Hg at all times if possible.

The use of pressors is generally discouraged in the initial resuscitation of multiple-trauma victims. Thus, the main focus associated with tracheal intubation.\textsuperscript{5} Finally, a small dose of a nondepolarizing neuromuscular agent, such as pancuronium, before administration of succinylcholine can protect against fasciculations, which may lead to a rise in ICP. The “defasciculation” dose is typically one tenth of the full paralytic dose of the agent. Box 73.2 presents a sample neuroprotective RSI strategy. It should be noted that although all the aforementioned adjuncts to RSI in patients with TBI are reasonable considerations, they should be implemented as part of a streamlined approach to TBI patients. The higher priority is rapid and safe intubation that avoids hypoxia and aspiration. If implementation of these adjuncts to traditional RSI results in delay or complications, all theoretic benefit is lost. Therefore, it is also reasonable to use traditional RSI in TBI patients without adjunctive medications.\textsuperscript{9}

The postintubation ventilation strategy significantly influences outcomes in patients with TBI. This reflects the adverse effects of positive pressure ventilation on cardiac output, hypocapnic cerebral vasoconstriction, and retrograde cerebral transmission of intrathoracic pressure via the jugular venous system, all of which can lead to cerebral hypoperfusion and ischemia. \( \text{Paco}_2 \) should be maintained asclose to normal as possible, within the range of 30 to 39 mm Hg.\textsuperscript{7} Hyperventilation does decrease ICP, but it does so by causing cerebral vasoconstriction and results in decreased cerebral blood.\textsuperscript{8} Transient hyperventilation, to a \( \text{Paco}_2 \) in the range of 30 to 35 mm Hg, is therefore reserved as a temporizing measure in the setting of acute deterioration as a means of avoiding herniation. Serial arterial blood gas analysis or \( \text{PETCO}_2 \) monitoring should be performed after intubation to ensure proper ventilation because traditional pulse oximetry monitoring reflects only oxygenation status.
STEROIDS IN PATIENTS WITH TRAUMATIC BRAIN INJURY
Corticosteroids do not improve outcome in TBI patients, and their use is associated with harmful complications. Steroids should not be administered as treatment of TBI.

MILD TRAUMATIC BRAIN INJURY

OVERVIEW
Current practice in EDs and trauma centers focuses on identifying TBI patients who require emergency neurosurgical intervention or close monitoring. However, about two thirds of patients with TBI in the United States sustain mild injury and are discharged home after a brief observation period. Mild TBI is generally defined as blunt injury to the head with resulting symptoms (which may or may not include loss of consciousness) and a GCS score higher than 13. For the emergency physician there are three important components of the management of every patient with mild TBI: when to image, disposition planning, and discharge instructions.

IMAGING
As discussed earlier, the modality of choice for the initial imaging of patients after TBI is non–contrast-enhanced CT. The prevalence of CT abnormalities is about 5% in patients arriving at the hospital with a GCS score of 15 and increases significantly with a lower initial GCS score. Approximately 1% of all patients with mild TBI ultimately require neurosurgical intervention. Several clinical decision rules designed to help clinicians decide which patients with mild TBI require imaging have been validated. Their recommendations differ because of variations in definitions and study populations. That said, certain features are consistently associated with intracranial pathology, such as older age, vomiting, focal neurologic deficit, and persistent alteration in level of consciousness. Recent consensus guidelines have been developed to guide imaging decisions and are summarized in Box 73.3.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

DISPOSITION
Patients suffering TBI who have abnormalities on head CT or persistent alteration in mental status should be admitted to a hospital with neurosurgical capability and be closely monitored for deterioration (Fig. 73.7). There is good evidence that patients with head injury who have normal findings on head CT and neurologic examination can be safely discharged from the ED without an extended observation period. It must be noted that the studies that came to this conclusion excluded certain populations, in particular, patients with bleeding disorders and those taking anticoagulant medications. Therefore, the data are insufficient to be certain that this recommendation is safe in these patients. We recommend a more careful approach to patients with acquired or inherited bleeding diatheses: either close observation in the hospital or discharge in the care of responsible caregivers who can watch the patient closely for signs of deterioration and have rapid access to return to the hospital for reevaluation. It is reasonable to include patients and their families in this decision and have an open discussion of the uncertainty in our understanding of the risk for deterioration in patients with TBI.

PATIENT TEACHING
The most important consideration when counseling patients sent home from the ED is to communicate the signs and symptoms of an evolving intracranial process, especially in patients who have not undergone CT imaging. Such signs and symptoms include worsening headache, persistent

---

BOX 73.3 Consensus Guidelines to Direct Imaging Decisions

A non–contrast-enhanced head computed tomography (CT) scan is indicated in head trauma patients with loss of consciousness or posttraumatic amnesia if one or more of the following is present:
- Glasgow Coma Scale score lower than 15
- Vomiting
- Age older than 60 years
- Drug or alcohol intoxication
- Deficits in short-term memory
- Physical evidence of trauma above the clavicle
- Posttraumatic seizure
- Headache
- Focal neurologic deficit
- Coagulopathy

A non–contrast-enhanced head CT scan should be considered in head trauma patients with no loss of consciousness or posttraumatic amnesia if one or more of the following is present:
- Focal neurologic deficit
- Vomiting
- Severe headache
- Age 65 years or older
- Physical signs of a basilar skull fracture
- Glasgow Coma Scale score lower than 15
- Coagulopathy
- Dangerous mechanism of injury
  - Ejection from a motor vehicle
  - Striking of a pedestrian
  - A fall from a height of more than 3 feet or 5 stairs

Fig. 73.7 Algorithm depicting the differential diagnosis of traumatic brain injury. CT, Computed tomography; GCS, Glasgow Coma Scale; RSI, rapid-sequence induction.

vomiting, confusion, and balance problems. Any of these findings should prompt return to the ED for immediate reevaluation and consideration of appropriate imaging studies.

It is also important to communicate to patients the possibility of postconcussive syndrome (PCS). This syndrome of persistent neurologic, behavioral, and cognitive symptoms develops in a substantial proportion of patients with mild TBI. Symptoms include headache, memory impairment, difficulty concentrating, anxiety, and depression. Of all patients with mild TBI, about 50% at 3 months and 15% at 1 year will have persistent PCS. Even though no specific treatments are available for PCS, early psychosocial intervention appears to reduce postconcussion symptoms and limit the emergence of persistent problems. Awareness can help validate symptoms that might otherwise not be attributed to the traumatic incident and lead to referral for neurorehabilitation or psychologic services or support groups.

CONCUSSION AND RETURN TO PLAY

The term concussion refers to short-lived impairment of neurologic function after trauma. Such impairment may or may not involve loss of consciousness and typically resolves over a sequential course, although postconcussive symptoms may be prolonged. A primary concern of emergency physicians and trainers is second-impact syndrome, which has been reported in athletes who return to play while still symptomatic from a concussion and sustain another head injury. These athletes, despite having mild symptoms and sustaining apparently mild second injuries, are at risk for the rapid development of brain swelling, herniation, and death. Additionally, athletes who sustain repeated concussions are at higher risk for long-term cognitive deficits. A stepwise progression of rehabilitation after concussion is recommended before return to play (Table 73.1), ideally supervised by an experienced athletic trainer or health care provider.

REFERENCES

The emergency physician needs to be able to accurately interpret and act on certain findings on computed tomography (CT) because many disease processes require immediate action. Even with a brief educational intervention, emergency physicians can significantly improve their ability to interpret cranial CT scans. Use the mnemonic “blood can be very bad” (where blood = blood, can = cisterns, be = brain, very = ventricles, and bad = bone) to quickly and thoroughly review a cranial CT scan for pathology. Magnetic resonance imaging offers excellent anatomic resolution and provides greater discrimination of various soft tissues than CT does.

PERSPECTIVE

Imaging of the central nervous system (CNS) has assumed a critical role in the practice of emergency medicine for the evaluation of intracranial emergencies, both traumatic and atraumatic. A number of studies have revealed a deficiency in the ability of emergency physicians (EPs) to interpret head computed tomography (CT) scans. However, a number of these same studies also show that with even brief educational effort, EPs can gain considerable proficiency in cranial CT scan interpretation. This is important because in many situations the EP must interpret and act on head CT results in real time without assistance from other specialists such as neurologists, radiologists, or neuroradiologists. Advantages of using these technologies for diagnosing CNS pathology in the emergency department (ED) include widespread availability at many institutions, speed of imaging, patient accessibility, and sensitivity in detecting many emergency pathologic processes.

COMPUTED TOMOGRAPHY

BASIC PRINCIPLES

The fundamental principle behind radiography is the following statement: x-rays are absorbed to different degrees by different tissues. Dense tissues such as bone absorb the most x-rays and hence allow the fewest to pass through the body part being studied to reach the film or detector. Conversely, tissues with low density (e.g., air, fat) absorb almost none of the x-rays, and most pass through to the film or detector. Conventional radiographs are two-dimensional images of three-dimensional structures; they rely on a summation of the density of tissues penetrated by x-rays as they pass through the body.

With CT scanning, an x-ray source and detector, situated 180 degrees across from each other, move 360 degrees around the patient while continuously detecting and sending information about the attenuation of x-rays as they pass through the body. Very thin x-ray beams are used to minimize the degree of scatter or blurring that limits conventional radiographs. In CT a computer manipulates and integrates the acquired data and assigns numeric values on the basis of subtle differences in x-ray attenuation. Based on these values, a gray-scale axial image is generated that can distinguish between objects with even small differences in density.

ATTENUATION COEFFICIENT

The tissue contained within each image unit (called a pixel) absorbs a certain proportion of the x-rays that pass through it (e.g., bone absorbs a lot, air almost none). The ability to block x-rays as they pass through a substance is known as attenuation. For a given body tissue, the amount of attenuation is relatively constant and is known as that tissue’s attenuation coefficient. In CT, these attenuation coefficients are mapped to an arbitrary scale of between −1000 Hounsfield units (HU) (air) and +1000 HU (bone) (Box 74.1). This scale is the Hounsfield scale (in honor of Sir Jeffrey Hounsfield, who received a Nobel Prize for his pioneering work with this technology).

WINDOWING

Windowing allows the CT scan reader to focus on certain tissues within a CT scan that fall within set parameters. Tissues of interest can be assigned the full range of blacks and

KEY POINTS

- The emergency physician needs to be able to accurately interpret and act on certain findings on computed tomography (CT) because many disease processes require immediate action.
- Even with a brief educational intervention, emergency physicians can significantly improve their ability to interpret cranial CT scans.
- Use the mnemonic “blood can be very bad” (where blood = blood, can = cisterns, be = brain, very = ventricles, and bad = bone) to quickly and thoroughly review a cranial CT scan for pathology.
- Magnetic resonance imaging offers excellent anatomic resolution and provides greater discrimination of various soft tissues than CT does.
Volume averaging (also called partial volume artifact) arises when the imaged area contains different types of tissue (e.g., bone and brain). For that particular image unit, the CT pixel produced will represent an average density for all the structures contained within it. In the instance of brain and bone, an intermediate density will be represented that may have the appearance of blood. As with beam hardening, certain techniques can minimize this type of artifact (e.g., thinner slices, computer algorithms), but it cannot be eliminated, particularly in the posterior fossa.

**NORMAL NEUROANATOMY AS SEEN ON HEAD COMPUTED TOMOGRAPHY**

As with radiologic interpretation of any body part, working knowledge of normal anatomic structures and location is fundamental to the clinician’s ability to detect pathologic variants. Paramount in head CT interpretation is familiarity with the various CNS structures, ranging from parenchymal areas, such as the basal ganglia, to vasculature structures, cisterns, and ventricles. Additionally, knowing the neurologic function of these regions of the brain helps when correlating CT results with findings on physical examination.

Although detailed knowledge of cranial neuroanatomy and its CT appearance is clearly in the realm of the neuroradiologist, familiarity with a relatively few structures, regions, and expected findings allows sufficient interpretation of most head CT scans by the EP. Figures 74.2 through 74.5 demonstrate key structures of a normal head CT scan.

**IDENTIFYING CENTRAL NERVOUS SYSTEM PATHOLOGY ON CRANIAL COMPUTED TOMOGRAPHY**

As long as one is systematic in the search for pathology, any number of techniques can be used when reviewing head CT images. Some recommend a “center-out” technique in which the examiner starts from the middle of the brain and works outward. Others advocate a “problem-oriented” approach in which the clinical history directs the examiner to a particular portion of the scan. In the author’s experience, both these approaches are of limited utility to clinicians who do not frequently review scans. A preferred method, one that has been demonstrated to work in the ED, is to use the mnemonic

whites rather than a narrow portion of the gray scale. With this technique, subtle differences in tissue densities can be maximized. The image displayed depends on both centering of the viewing window and the width of the window. Most CT imaging includes windows that are optimized for brain, blood, and bone (Fig. 74.1).

**ARTIFACT**

CT of the brain is subject to a few predictable artifactual effects that can potentially inhibit the ability to accurately interpret the images. Besides motion and metal artifact (self-explanatory), the two most common effects are called beam hardening and volume averaging. It is important to understand these artifactual effects and to be able to identify them because they can mimic pathology, as well as obscure actual significant findings.

Beam hardening is a phenomenon that causes an abnormal signal when a relatively small amount of hypodense brain tissue is immediately adjacent to dense bone. The posterior fossa, where extremely dense bone surrounds the brain, is particularly subject to this phenomenon. It appears as either linear hyperdensities or hypodensities that can partially obscure the brainstem and cerebellum. Although beam hardening can be reduced with appropriate filtering, it cannot be eliminated.

**Fig. 74.1 CT scan windowing. A, Brain. B, Blood. C, Bone.**

“blood can be very bad” (Box 74.2). In this mnemonic, the first letter of each word prompts the clinician to search a certain portion of the CT scan for pathology.

**Blood**

The appearance of blood on a head CT scan depends primarily on its location and amount. Acute hemorrhage will appear hyperdense (bright white) on cranial CT images. This is attributed to the fact that the globin molecule is relatively dense and hence effectively absorbs x-ray beams. Acute blood is typically in the range of 50 to 100 HU. As the blood becomes older and the globin molecule breaks down, it will lose this hyperdense appearance, beginning at the periphery and working in centrally. On CT scans, blood will become isodense relative to brain tissue at 1 to 2 weeks, depending on clot size, and will become hypodense relative to brain tissue at approximately 2 to 3 weeks (Fig. 74.6).

Precise localization of the blood is as important as identification of its presence (Fig. 74.7). Epidural hematomas, subdural hematomas, intraparenchymal hemorrhage, and subarachnoid hemorrhage each have a distinct appearance on CT, as well as different causes, complications, and associated conditions.

**EPIDURAL HEMATOMA** Epidural hematoma most frequently appears as a lens-shaped (biconvex) collection of blood, usually over the brain convexity. An epidural hematoma will not cross a suture line because the dura is tacked down in these areas. Epidural hematomas arise primarily (85%) from arterial laceration as a result of a direct blow, with the middle meningeal artery being the most common source. A small proportion, however, come from other injured arteries and can even be venous in origin.

**SUBDURAL HEMATOMA** Subdural hematoma appears as a sickle- or crescent-shaped collection of blood, usually over the cerebral convexity. Subdural hematomas can also be seen as isolated collections that appear in the interhemispheric...
BOX 74.2 The “Blood Can Be Very Bad” Mnemonic*

Blood—Acute hemorrhage appears hyperdense (bright white) on computed tomography. The globin molecule is relatively dense and effectively absorbs x-ray beams. As the blood ages, the globin molecule breaks down and loses its hyperdense appearance, beginning at the periphery. Precise localization of the blood is as important as identification of its presence.

Cisterns—Cerebrospinal fluid collections in the brain. The four key cisterns must be examined for blood, asymmetry, and effacement (representing increased intracranial pressure):
- Circummesencephalic—Cerebrospinal fluid ring around the midbrain; it is the first to be effaced with increased intracranial pressure
- Suprasellar (star-shaped)—Location of the circle of Willis; this is a frequent site of aneurysmal subarachnoid hemorrhage
- Quadrigeminal—W-shaped cistern at the top of the midbrain; it is effaced early by rostrocaudal herniation
- Sylvian—Between the temporal and frontal lobes; this is the site of traumatic and distal midcerebral aneurysm and subarachnoid hemorrhage

Brain—Examine for:
- Symmetry—The sulcal pattern (gyri) is well differentiated in adults and symmetric side to side.
- Gray-white differentiation—The earliest sign of cerebrovascular aneurysm is loss of gray-white differentiation; metastatic lesions are often found at the gray-white border.
- Shift—The falx should be midline, with the ventricles evenly spaced to the sides; it can also have a rostrocaudal shift, as evidenced by loss of cisternal space; unilateral effacement of the sulci signals increased pressure in one compartment; bilateral effacement signals globally increased pressure.
- Hyperdensity/hypodensity—Increased density with blood, calcification, intravenous contrast media; decreased density with air or gas (pneumocephalus), fat, ischemia (cerebrovascular aneurysm), tumor.

Ventricles—Pathologic processes cause dilation (hydrocephalus) or compression or shifting; hydrocephalus is usually first evident with dilation of the temporal horns (normally small and slitlike); the examiner must assess the “whole picture” to determine whether the ventricles are enlarged because of lack of brain tissue or increased cerebrospinal fluid pressure.

Bone—Highest density on computed tomography; diagnosis of skull fractures can be confusing because of the presence of sutures in the skull; compare with the other side of the skull for symmetry (suture) versus asymmetry (fracture); basilar skull fractures are commonly found in the petrous ridge (look for blood in the mastoid air cells)

*Blood = blood; Can = cisterns; Be = brain; Very = ventricles; Bad = bone.

---

**Fig. 74.7** CT appearance of blood in patients with hematoma. **A**, Epidural hematoma. **B**, Subdural hematoma. **C**, Intraparenchymal and intraventricular hematomas.

Fissures or along the tentorium. As opposed to epidural hematomas, subdural hematomas will cross suture lines because there is no anatomic limitation to blood flow below the dura. A subdural hematoma can be either acute or chronic. Although both result primarily from disruption of surface or bridging vessels, the magnitude of impact damage is usually much higher with acute lesions. Thus, they are frequently accompanied by severe brain injury, which contributes to a much poorer overall prognosis than seen with epidural hematoma. Chronic subdural hematoma, in contrast, usually follows a more benign course than acute subdural hematoma does. Attributed to slow venous oozing after even a minor closed
head injury, the clot can accumulate gradually, which allows the patient time to compensate. Because the clot is frequently encased in a fragile vascular membrane, however, these patients are at significant risk for rebleeding after additional minor trauma. The CT appearance of a chronic subdural hematoma depends on the length of time since the initial bleeding. A subdural hematoma that is isodense with respect to brain tissue can be very difficult to detect on CT, and in these cases contrast enhancement may highlight the surrounding vascular membrane.

INTRAPARENCHYMAL HEMORRHAGE Cranial CT can reliably identify intraparenchymal (or intracerebral) hematomas as small as 5 mm. They appear as high-density areas on the CT scan, usually with much less mass effect than their apparent size would indicate. Traumatic intraparenchymal hematomas may be seen immediately following an injury, or they can appear in delayed fashion, after sufficient time for swelling has elapsed. Additionally, contusions may enlarge and coalesce over first 2 to 4 days. Traumatic contusions most commonly occur in areas where sudden deceleration of the head causes the brain to impact on bony prominences (e.g., temporal, frontal, occipital poles).

In distinction to traumatic lesions, nontraumatic hemorrhagic lesions caused by hypertensive disease are typically seen in elderly patients and occur most frequently in the basal ganglia region. Hemorrhage from such lesions may rupture into the ventricular space, with the additional finding of intraventricular hemorrhage on CT. Posterior fossa bleeding (e.g., cerebellar) may dissect into the brainstem (pons, cerebellar peduncles) or rupture into the fourth ventricle. Besides hypertensive causes, intraparenchymal hemorrhage can be caused by arteriovenous malformations, bleeding from or into a tumor, amyloid angiopathy, or aneurysms that happen to rupture into the substance of the brain rather than into the subarachnoid space.

INTRAVENTRICULAR HEMORRHAGE Intraventricular hemorrhage can be traumatic in origin or secondary to intraparenchymal hemorrhage or subarachnoid hemorrhage with ventricular rupture. Identified as a white density in the normally black ventricular spaces, it is associated with a particularly poor outcome in cases of trauma (although this may be more of a marker than a causative issue). Hydrocephalus can be the end result regardless of the cause. Cerebrospinal fluid (CSF) is produced in the lateral ventricles at a rate of 0.5 to 1 mL/min, and such production will occur regardless of intraventricular pressure. A block at any point in the CSF pathway (lateral ventricles \(\rightarrow\) foramen of Monro \(\rightarrow\) third ventricle \(\rightarrow\) aqueduct of Sylvius \(\rightarrow\) fourth ventricle \(\rightarrow\) foramina of Luschka and Magendie \(\rightarrow\) cisterns \(\rightarrow\) arachnoid granulations) will result in hydrocephalus and the potential for herniation.

SUBARACHNOID HEMORRHAGE Subarachnoid hemorrhage is defined as hemorrhage into any subarachnoid space that is normally filled with CSF (e.g., cistern, brain convexity). The hyperdensity of blood in the subarachnoid space is frequently visible on CT imaging within minutes of the onset of hemorrhage (Fig. 74.8). Subarachnoid hemorrhage is most commonly aneurysmal (75% to 80%), but it can also occur with trauma, tumor, arteriovenous malformations, and dural malformations. As a result of arachnoid granulations becoming plugged with red blood cells or their degradation products, hydrocephalus complicates approximately 20% of cases of subarachnoid hemorrhage.

The ability of a CT scanner to demonstrate subarachnoid hemorrhage depends on a number of factors, including the generation of scanner, the time since the initial bleeding, and the skill of the examiner. According to some studies, CT is 95% to 98% sensitive for subarachnoid hemorrhage in the first 12 hours after the ictus. This sensitivity is reported to decrease as follows:

90% to 95% at 24 hours
80% at 3 days
50% at 1 week
30% at 2 weeks
EXTRACRANIAL HEMORRHAGE  The presence and significance of extracranial blood and soft tissue swelling on CT imaging are often overlooked. The examiner should use this finding to lead to subtle fractures that can be identified in areas of maximal impact (and hence maximal soft tissue swelling). This will also direct the examiner to search the underlying brain parenchyma in these areas for parenchymal contusions, as well as to areas opposite maximal impact to search for contrecoup injuries.

Cisterns  Cisterns are potential spaces that form where CSF pools as it works its way up to the superior sagittal sinus from the fourth ventricle. Of the numerous named cisterns (and some with multiple names), the EP needs to be familiar with four key cisterns to identify increased intracranial pressure, as well as the presence of blood in the subarachnoid space (Fig. 74.9). These cisterns are as follows:

- Circummesencephalic—Hypodense CSF ring around the midbrain; most sensitive marker for increased intracranial pressure; will become effaced first with increased pressure and herniation syndromes
- Suprasellar—Star-shaped hypodense space above the sella and pituitary; location of the circle of Willis and hence an excellent location for identifying aneurysmal subarachnoid hemorrhage
- Quadrigeminal—W-shaped cistern at the top of the midbrain; can be a location for identifying traumatic subarachnoid hemorrhage, as well as an early marker of increased intracranial pressure and rostrocaudal herniation (Fig. 74.10)
- Sylvian—Bilateral CSF space located between the temporal and frontal lobes of the brain; another good location to identify subarachnoid hemorrhage, whether caused by trauma or aneurysmal leakage (particularly distal middle cerebral artery aneurysms)

Brain  Normal brain parenchyma has an inhomogeneous appearance where the gray and white matter interface. Because cortical gray matter is denser than subcortical white matter, the cortex will appear lighter on CT imaging. Many disease processes are unilateral (e.g., cerebrovascular aneurysm, tumor, abscess), and thus particular attention should be paid to side-to-side symmetry on the scan. Gyral and sulcal patterns should be symmetric (Fig. 74.11). It is also important to examine the brain parenchyma for the following:

- Gray-white differentiation—The earliest sign of an ischemic cerebrovascular aneurysm will be loss of gray-white
Fig. 74.10  CT appearance of increased intracranial pressure as noted by compression of the quadrigeminal cistern (arrows).  

Fig. 74.11  CT appearance of a normal brain.

differentiation. Tumors can also obscure this interface, particularly when associated edema is present (hypodensity).

• Shift—The falx should be midline and the ventricles evenly spaced to the sides. With rostrocaudal herniation the midline will be preserved, but this will usually be evidenced by loss of cisternal spaces. Unilateral effacement of the sulci signals increased pressure in one compartment. Bilateral effacement signals globally increased pressure.

• Hyperdensity/hypodensity—Brain will take on increased density with blood, calcification, and intravenous contrast media. It will take on decreased density with air (pneumocephalus), water, fat, and ischemia (cerebrovascular accident). Tumor may result in either increased or decreased density on CT imaging, depending on the type of tumor and amount of edema.

SPECIFIC BRAIN PARENCHYMAL LESIONS

Tumor  Brain tumors usually appear as hypodense, poorly defined lesions on non-contrast-enhanced CT. It is estimated that 70% to 80% of brain tumors will be apparent on plain scans without the use of an intravenous contrast agent. The calcification and hemorrhage associated with a tumor can cause it to have a hyperdense appearance. Tumors should be suspected on a non-contrast-enhanced CT scan when significant edema is associated with an ill-defined mass. This vasogenic edema is due to loss of integrity of the blood-brain barrier, which allows fluid to pass into the extracellular space. Edema, because of the increased water content, appears hypodense on CT (Fig. 74.12).

Intravenous contrast material can help define brain tumors. Contrast media will leak through the incompetent blood-brain barrier into the extracellular space surrounding the mass lesion and result in a contrast-enhancing ring. Once a tumor is identified, the clinician should make some determination of the following information: location and size—intraaxial (within the brain parenchyma) or extraaxial; and degree of edema and mass effect—for example, herniation may be impending because of swelling.

Abscess  A brain abscess appears as an ill-defined hypodensity on non-contrast-enhanced CT. A variable amount of edema is usually associated with such lesions, and like tumors, they frequently demonstrate ring enhancement with the addition of an intravenous contrast agent.

Ischemic Infarction  Strokes are classified as either hemorrhagic or nonhemorrhagic. Nonhemorrhagic infarctions can be seen as early as 2 to 3 hours following ictus, but most will
the brain because the ventricles can be large for reasons other than increased pressure (e.g., atrophy). If the ventricles are large, the clinician should investigate whether other CSF spaces in the brain are large (e.g., sulci, cisterns). This can be a result of loss of brain volume rather than an increase in ventricular size. Conversely, if the ventricles are large but the brain appears “tight” with sulcal and cisternal effacement and loss of sulcal space, the likelihood of hydrocephalus is high.

**Bone**

As demonstrated earlier, bone has the highest density on CT (+1000 HU). Consequently, depressed or comminuted skull fractures can usually be easily identified on CT; however, small linear (nondepressed) skull fractures and fractures of the skull base may be more difficult to find (Fig. 74.15). Additionally, diagnosing fractures can be confusing because of the presence of sutures in the skull. Fractures may occur at any portion of the skull. The presence of a fracture should increase the index of suspicion for other intracranial injury. If intracranial air is seen on CT, this indicates that the skull and dura have been violated at some point (Fig. 74.16). Basilar skull fractures are most commonly found in the petrous ridge (the dense pyramidal-shaped portion of the temporal bone). Because of the density of this bone, the fracture line may not be easily identified in this area. The clinician should not only search for such a fracture line but also pay close attention to the normally aerated mastoid air cells that are contained within this bone. Any blood in the mastoid air cells means that a skull base fracture is likely. Analogous to the mastoid air cells, the maxillary, ethmoid, and sphenoid sinuses should be visible and aerated; the presence of fluid in any of these sinuses in the setting of trauma should not begin to be clearly evident on CT scans for 12 to 24 hours. The earliest change seen in areas of ischemia is loss of gray-white differentiation as a result of influx of water into the gray matter. Because gray matter is metabolically more active than white matter, the gray cells are affected first, become edematous, and take on the CT appearance of white matter. This loss of gray-white differentiation may initially be a subtle finding but will become more pronounced, with peak findings becoming evident between 3 and 5 days (Fig. 74.13).

Any vascular distribution can be affected by ischemic lesions (e.g., middle cerebral artery, posterior inferior cerebellar artery). One specialized type of stroke frequently identified on CT imaging is a lacunar infarction, which consists of small, discrete nonhemorrhagic lesions usually secondary to hypertension and found in the basal ganglia region. They are often clinically silent.

**Ventricles**

Pathologic processes can cause either dilation (hydrocephalus) or compression or shifting of the ventricular system (Fig. 74.14). Additionally, hemorrhage can occur into any of the ventricles and result in the potential for obstruction of flow and subsequent hydrocephalus. The term communicating hydrocephalus is used when CSF freely egresses from the ventricular system with blockage at the level of the arachnoid granulations. The term noncommunicating hydrocephalus is used if obstruction occurs anywhere along the course of flow from the lateral ventricles through egress from the fourth ventricle. Hydrocephalus is frequently first evident with dilation of the temporal horns, which are normally small with a slitlike morphology.

When examining the ventricular system for hydrocephalus, the clinician needs to consider the entire picture of
emit a signal that forms the image. The frequency of the radiowave emitted is related to the density and location of the proton and discriminates one tissue from another. For example, certain radiofrequency pulse sequences may be used to acquire clearer images of dense tissue, blood vessels, or other fluid-filled structures.

Although many MRI techniques exist, the two basic types of imaging sequences are T1 and T2. T1 and T2 images demonstrate the local tissue relaxation time that follows a radio-wave pulse and thus reflect the three-dimensional molecular environment that surrounds each proton. For example, brain tissue contains intracellularly bound water and has shorter T1 and T2 times than do tissues with larger amounts of extracellular water, such as most neoplasms. (Figs. 74.17 and 74.18).

T1 is a measure of the proton’s ability to exchange energy with its surroundings. In other words, T1 is a measure of how quickly the tissue can become magnetized. T1-weighted also raise suspicion for a skull fracture. In nontraumatic cases, fluid in the mastoids may indicate mastoiditis, and fluid in the sinuses may indicate sinusitis.

## MAGNETIC RESONANCE IMAGING

### BASIC PRINCIPLES

Unlike CT, magnetic resonance imaging (MRI) technology does not use ionizing radiation. Instead, images are created via magnetic fields and radiowaves. First, a strong magnetic field causes alignment of the magnetic poles of hydrogen nuclei (protons). The hydrogen nucleus is targeted because of its abundance in water and fat. A brief radiofrequency stimulus is then applied to the area being studied and causes a disruption in the magnetic alignment of the protons. The protons then return to their baseline state, during which they emit a signal that forms the image. The frequency of the radiowave emitted is related to the density and location of the proton and discriminates one tissue from another. For example, certain radiofrequency pulse sequences may be used to acquire clearer images of dense tissue, blood vessels, or other fluid-filled structures.

Although many MRI techniques exist, the two basic types of imaging sequences are T1 and T2. T1 and T2 images demonstrate the local tissue relaxation time that follows a radio-wave pulse and thus reflect the three-dimensional molecular environment that surrounds each proton. For example, brain tissue contains intracellularly bound water and has shorter T1 and T2 times than do tissues with larger amounts of extracellular water, such as most neoplasms. (Figs. 74.17 and 74.18).
images show fat as a white or bright signal, whereas water or CSF is dark. T2 measures how quickly tissue loses magnetization. On a T2-weighted image, fat is dark, and blood, edema, and CSF appear white. Contrast dye such as gadolinium may also be used to enhance organs and accentuate pathology by shortening the T1 and T2 relaxation times of the hydrogen nuclei (Fig. 74.19).

Other commonly used radio wave pulse sequences include STIR (short time of inversion recovery) and FLAIR (fluid-attenuated inversion recovery). STIR sequencing is used to emphasize differences in T1 images and accentuate tissue with high water content while suppressing fat signal. STIR images are especially useful in spinal and joint imaging. For example, suppressed signal from bone marrow and surrounding fat allows bone tumors to be visualized more clearly. The FLAIR technique suppresses the T1 signals generated by fluid to better identify adjacent tissue abnormalities (Fig. 74.20). FLAIR is useful for differentiating
periventricular and spinal cord edema from CSF. The signal from CSF is nulled and appears darker in water-suppressed images.

**MAGNETIC RESONANCE IMAGING VERSUS COMPUTED TOMOGRAPHY**

In general, MRI offers excellent anatomic resolution and provides greater discrimination of various soft tissues than CT does. For example, MRI provides clear images of the CNS and stationary soft tissues such as the shoulder or knee joints. In addition, many diseases are characterized by an increase in localized water content, for which MRI is sensitive in detecting. MRI is more sensitive than CT for diagnosing inflamed tissue secondary to cerebral ischemia, infection, or malignancy. MRI and CT are both sensitive in detecting acute hemorrhage; however, MRI is much more sensitive in detecting subacute or chronic hemorrhage, which may be less apparent on CT.

Disadvantages of MRI include cost, artifact because of patient motion, and inability to bring metallic objects into the room. MRI requires a cooperative patient but may induce claustrophobia in some patients. Finally, MRI often requires more time to perform than CT does, and immediate access to life support equipment is frequently limited.

Spine Trauma and Spinal Cord Injury

Michelle Lin and Swaminatha V. Mahadevan

**KEY POINTS**

- Patients with spinal pain and spine fractures should receive a thorough neurologic examination to look for spinal cord injury.
- Spine fractures are associated with a high incidence of concurrent noncontiguous spine fractures and spinal cord injuries.
- The National Emergency X-radiography Utilization Study criteria or the Canadian Cervical-Spine Rule criteria can be used to identify low-risk patients who do not need cervical spine imaging.
- Imaging with plain films versus computed tomography of the cervical spine should be based on the pretest probability of a significant injury and the irradiation risk with computed tomography.
- Spinal shock, or transient physiologic transection of the spinal cord as a result of trauma, is different from neurogenic shock, which is physiologic sympathectomy of the upper spinal cord leading to peripheral vasodilation.
- Patients with a spinal cord injury caused by blunt trauma are often given high-dose corticosteroids within 8 hours of injury, although such therapy is controversial.

**EPIDEMIOLOGY**

The estimated annual cost of spine injuries, including inability to work and health care costs, exceeds $5 billion in the United States. In the emergency department (ED), all trauma victims are screened for vertebral fractures, ligamentous disruptions, and spinal cord injuries because of the potentially devastating neurologic consequences of overlooking these injuries. Patients with a delayed diagnosis of spinal fracture are 7.5 times more likely to sustain secondary neurologic deficits. Neurologic deficits from spinal cord injury may be subtle and can easily be missed if not specifically evaluated. Adding to these difficulties, plain film radiographs of the spine, though an adequate screening tool for other fractures, can miss 23% to 42% of cervical spinal fractures and 13% to 50% of lumbar fractures.

**PATHOPHYSIOLOGY**

In the setting of spinal trauma, the bone, ligaments, spinal cord, and vascular structures may be injured. Anatomically, the vertebral bony spine can be divided into structural columns. The cervical spine is traditionally divided into two columns—anterior and posterior. The anterior column consists of the load-bearing vertebral bodies, intervertebral disks, anterior longitudinal ligament, and posterior longitudinal ligament (Fig. 75.1). The posterior column consists of the more posterior structures, including the pedicles, laminae, and transverse and spinous processes (Fig. 75.2).

In contrast, the thoracic and lumbar vertebral spines are divided into three columns based on the modified Denis model—anterior, middle, and posterior (Fig. 75.3). The anterior column consists of the anterior longitudinal ligament, the anterior two thirds of the vertebral body, and the intervertebral disk. The middle column consists of the posterior longitudinal ligament, the posterior third of the vertebral body, and the intervertebral disk. Any disruption of the middle column predisposes a patient to significant spinal cord injury because the middle column abuts the spinal canal. The posterior column consists of the remaining posterior structures.

The C1 and C2 vertebrae are anatomically unique (Fig. 75.4). C1 (atlas) is a ring-link structure without a vertebral body. It articulates superiorly with the occipital condyles. This articulation allows 50% of normal neck flexion and extension. C2 (axis) projects the dens superiorly to articulate with C1. The transverse ligament tethers the dens to the anterior arch of C1. This atlantoaxial articulation allows 50% of normal neck rotation left and right.

The spinal cord spans from the foramen magnum to the L1 level, whereupon the spinal cord tapers into the conus medullaris and cauda equina, a collection of peripheral lower lumbar and sacral nerve roots. Because the spinal cord is thickest in the cervical spine, there is relatively less spinal canal space in the cervical levels than in the thoracic or lumbar spine. Thus spinal cord injuries occur more frequently with cervical spine trauma than with thoracic or lumbar spine trauma. The neurologic dermatomes can help localize the injury (Table 75.1).

The vertebral arteries branch off the subclavian arteries and course superiorly within the transverse foramina of C2 to C6. These arteries then merge to form the basilar artery.
Patients with spinal cord injuries may have a spectrum of findings ranging from subtle neurologic deficits to grossly obvious paralysis. Spinal cord injuries should be suspected in any trauma victim who complains of neck or back pain, especially pain exacerbated by movement. Neurologic symptoms suggesting spinal cord injury include numbness, tingling, paresthesias, focal weakness, and paralysis. Other worrisome symptoms include urinary or fecal incontinence and urinary retention. Unconscious patients and those with impaired consciousness secondary to intoxication may harbor occult spinal cord injuries. Physical examination should focus on the spine and areas where associated injuries may occur (Tables 75.2 to 75.4).

**PRESENTING SIGNS AND SYMPTOMS**

Patients with vertebral fractures usually have significant midline spinal tenderness on palpation. High-risk findings include spinal soft tissue swelling, ecchymosis, and step-off misalignment of the spine. Pain radiating along a dermatomal distribution suggests an associated radiculopathy. Thoracic spine fractures are uncommon because the articulating ribs provide stability to the spinal column; however, the thoracolumbar junction (encompassing the T10 to L2 vertebral levels) is commonly injured because the spine curvature changes from the kyphotic thoracic spine to the lordotic lumbar spine.

Table 75.2 Physical Examination Findings Associated with Vertebral Fractures and Spinal Cord Injuries

<table>
<thead>
<tr>
<th>INJURY</th>
<th>PHYSICAL EXAMINATION AREA</th>
<th>ASSOCIATED FINDINGS</th>
</tr>
</thead>
</table>
| Vertebral fracture | Spine | Tenderness of the neck and/or back. Examine the entire spine because vertebral fractures may occur in multiples.
Neurologic | Chest | See spinal cord injury below.
Thoracic spine fractures: Check for chest tenderness, unequal breath sounds, and arrhythmia, which are suggestive of an associated intrathoracic injury or myocardial contusion.
Thoracolumbar and lumbar spine fractures: Check for abdominal or pelvic tenderness. For instance, up to 50% of patients with a transverse process fracture and 33% of patients with a Chance fracture have concurrent intraabdominal pathology. A transverse area of ecchymosis on the lower abdominal wall (seat belt sign) increases the chance of an abdominopelvic injury.
Extremity | Thoracolumbar and lumbar spine fractures: Check for calcaneal tenderness because 10% of calcaneal fractures are associated with a low thoracic or lumbar fracture. Mechanistically, these areas are fractured as a result of axial loading. |
| Neurologic, motor (anterior column) | Assess motor function on a scale of 0 to 5 (see Table 75.3). Motor level is defined as the most caudal segment with at least 3/5 strength. Injuries to the first eight cervical segments result in tetraplegia (previously known as quadriplegia); lesions below the T1 level result in paraplegia. |
Neurologic, sensory (spinothalamic tract) | Assess sensory function via pinprick and light touch on the following scale: 0 = absent; 1 = impaired; 2 = normal. The sensory level is defined as the most caudal segment of the spinal cord with normal sensory function. The highest intact sensory level should be marked on the patient’s spine to monitor for progression. |
| Neurologic, sensory (dorsal column) | Assess vibratory sensory function on a scale of 0 to 2 by using a tuning fork over bony prominences. Assess position sense (proprioception) by flexing and extending the great toe. On a scale of 0 to 4, assess the deep tendon reflexes in the upper (biceps, triceps) and lower (patellar, Achilles) extremities (see Table 75.4). |
Neurologic, motor (anterior column) | Assess rectal tone, sacral sensation, signs of urinary or fecal retention or incontinence, and priapism. Also check the anogenital reflexes: an anal wink (S2-S4) is present if the anal sphincter contracts in response to stroking the perianal skin area. The bulbocavernosus reflex (S3-S4) is elicited by squeezing the glans penis or clitoris (or pulling on an inserted Foley catheter), which results in reflexive contraction of the anal sphincter. |
Neurologic, sensory (dorsal column) | A spinal cord injury may mask a patient’s ability to perceive and localize pain. Imaging of high-risk areas, such as the abdomen, and areas of bruising or swelling may be required to exclude occult injuries. |
Spinal shock is a neurologic phenomenon resulting from physiologic transection of the spinal cord. It results in flaccid paralysis and loss of reflexes below the level of the spinal cord lesion. Spinal shock is temporary, commonly lasting for 24 to 48 hours, although it can persist for weeks. Patients suffering from spinal shock may appear (clinically) to have a complete spinal cord injury only to “miraculously” recover once the spinal shock has passed. Termination of spinal shock is identified by return of segmental reflexes; anogenital reflexes are the earliest to recover.

Neurogenic shock may occur in patients with cervical or high thoracic spinal cord injuries. It is a neurocardiovascular phenomenon resulting from impairment of the descending sympathetic pathways in the spinal cord. As a result, vasomotor tone is lost and visceral and peripheral vasodilation and hypotension ensue. Diminished sympathetic innervation to the heart also occurs and results in relative bradycardia despite the presence of hypotension.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

**INDICATIONS FOR CERVICAL SPINE IMAGING**

In the year 2000, in the hope of reducing the number of low-risk patients undergoing cervical spine plain film radiography, a multicenter study by the National Emergency X-radiography Utilization Study (NEXUS) group validated a set of five low-risk criteria for determining which patients do not require radiographic imaging if all the criteria are met (Box 75.1). This clinical decision tool demonstrated a sensitivity of 99.6% and a specificity of 12.9% for detecting clinically significant cervical spine fractures. It was thus extrapolated that 4309 (12.6%) of the 34,069 patients enrolled could have avoided plain film radiography.

Following development of the NEXUS criteria, the Canadian Cervical-Spine Rule (CCR) was developed (Fig. 75.5). The validated sensitivity and specificity for this decision rule were 99.4% and 45.1%, respectively.

The CCR study excluded the following subjects: patients younger than 16 years; patients with an abnormal Glasgow Coma Scale score, abnormal vital signs, injuries more than 48 hours old, penetrating trauma, paralysis, and history of vertebral disease; patients seen previously for the same injury; and pregnant patients. Because these cases were not studied, the CCR guidelines should not be applied to such patients.

**CHOOSING THE IMAGING MODALITY TO EVALUATE THE CERVICAL SPINE** (Fig. 75.6)

When patients have at least one high-risk criterion for a spinal fracture, imaging begins with either plain films or computed tomography (CT) scans. The pros and cons of both imaging approaches are listed in Table 75.5.

Patients with symptoms suggestive of a spinal cord injury should undergo CT and magnetic resonance imaging (MRI) of suspicious areas of the spine. Although plain films and CT do not directly reveal spinal cord injuries, they may supply indirect evidence of such injuries. Spinal cord injury without radiographic abnormality (SCIWORA) is a traumatic myelopathy in which no abnormalities can be identified on plain films or CT.

**Computed Tomography**

With increasing evidence in the literature showing that CT is much more sensitive (98%) than plain film radiography (53%) in detecting cervical spine fractures, future recommendations will probably recommend cervical spine CT as the first-line diagnostic approach for most patients because of the neurologic significance of a missed cervical spine injury. Conventional radiography is especially difficult to interpret in the high cervical spine (occiput, C1, C2) and cervicothoracic
CHAPTER 75  SPINE TRAUMA AND SPINAL CORD INJURY

Fig. 75.5  Canadian Cervical-Spine Rule (CCR) algorithm for clinical clearance of the cervical spine. The green box signifies a low-risk, negative work-up and clinical cervical spine clearance. Orange boxes signify a moderate-risk condition, and the red box signifies a high-risk condition, both of which require plain film radiography. ED, Emergency department; GCS, Glasgow Coma Scale; RR, respiratory rate; SBP, systolic blood pressure. (Data from Stiell IG, Clement CM, McKnight RD, et al. The Canadian C-Spine Rule versus the NEXUS low-risk criteria in patients with trauma. N Engl J Med 2003;349:2510-8.)

The risk for cancer from irradiation serves as the major deterrent against universally performing CT in all patients with neck trauma. It is estimated that up to 2% of cancers in the United States are attributable to CT studies. The thyroid gland, breast tissue, and lens are exposed to especially high levels of radiation in cervical spine CT, thus placing the patient at high risk for the development of thyroid cancer, breast cancer, and cataracts. Patients receive an effective dose of 0.2 millisievert (mSv) and 6 mSv for cervical spine plain films and CT, respectively. In contrast, the effective dose of a posteroanterior and lateral chest radiograph is just 0.1 mSv. The overall lifetime carcinogenic risk from CT imaging, however, varies depending on the patient’s age at the time of irradiation. Younger patients have greater risk, partly because they have more years of life left for the development of cancer.
**Fig. 75.6** Diagnostic algorithm for a patient with neck pain resulting from blunt trauma. *CCR*, Canadian Cervical-Spine Rule; *CT*, computed tomography; *MRI*, magnetic resonance imaging; *NEXUS*, National Emergency X-radiography Utilization Study.
Furthermore, children are more radiosensitive. If irradiated after 40 years of age, the risk reaches its nadir, with an estimated lifetime attributable risk for death from cancer of less than 0.2%.14

Because of such concerns for radiation exposure, low-risk patients should undergo conventional radiography. Only patients with radiographic evidence of an injury on plain films should subsequently undergo CT scanning. For moderate- to high-risk patients, cervical spine CT should be the first-line imaging modality, especially for patients scheduled for CT scanning of another body part.

Flexion-Extension Plain Film Radiography
A normal cervical image adequately excludes a cervical spine fracture but cannot sufficiently evaluate ligamentous instability. In patients who have sustained significant flexion, extension, or rotational injury to the neck and have persistent neck pain, ligamentous stability should be assessed within 10 days either in the ED or by a neurosurgeon or orthopedic spine specialist.

In the ED, patients who are awake and alert and can actively flex and extend their neck 30 degrees may undergo flexion-extension plain film radiography to evaluate for spinal stability. Vertebral body subluxation or focal widening of the spinous processes suggests an unstable ligamentous injury. Because no serious adverse outcomes have resulted from voluntary neck movement by an awake, alert patient without neurologic deficits, manual manipulation of the patient’s neck should be avoided during flexion-extension radiography.

Many acutely injured patients have such severe associated cervical muscle spasms that they have limited neck mobility. As a result, flexion-extension films are often inadequate, and these patients should be immobilized in a semirigid cervical collar (e.g., a Philadelphia or Miami J collar) and undergo delayed flexion-extension plain film radiography after 7 to 10 days, when the cervical muscle spasm diminishes.

### Magnetic Resonance Imaging
MRI is the best available modality for detection and characterization of spinal cord injury, but it is less sensitive than CT for cervical spine fractures. In an acute trauma patient with potential spinal injury, indications for emergency MRI include (1) complete or incomplete neurologic deficits suspicious for a spinal cord injury, (2) deterioration of spinal cord neurologic function, and (3) signs of unstable ligamentous injury. Abnormal MRI findings may include the presence of spinal canal compromise, disk herniation, and spinal cord edema or hemorrhage.

### Older and Osteopenic Patients
Patients older than 65 years old and those taking corticosteroids on a long-term basis are probably osteopenic. They can sustain spinal fractures with mild trauma, such as a fall from a standing position, and often exhibit minimal associated pain. Specifically, patients older than 65 years have an increased risk for cervical spine fracture (relative risk of 2.09). In addition, acute back pain in chronic corticosteroid users is correlated with 99% specificity for a spinal compression fracture.17 Thus, imaging should be performed in these potentially osteopenic patients in the setting of neck or back pain.

### Clinical Clearance of the Cervical Spine
Not all patients require cervical spine imaging. To clinically clear a cervical spine, the patient’s neck should be reevaluated for tenderness. First, unfasten the cervical collar. Next, palpate the posterior aspect of the patient’s neck while applying the other hand to the patient’s forehead to prevent spontaneous and reflexive head lifting. In the absence of significant midline tenderness, remove your hands and instruct the patient to actively lift the head off the gurney and place the neck through a range of motion by looking right, left, caudad, and cephalad. Do not assist the patient.

If the patient is able to move spontaneously and easily without pain or neurologic symptoms, the patient’s neck is considered to be “clinically cleared” and the collar may be removed.
Ten percent of spinal fractures have a second noncontiguous fracture along the vertebral spine.
Ten percent of patients with a calcaneal fracture have an associated thoracic or lumbar fracture.
The most commonly fractured cervical spine level is C2, especially in the elderly.
Approximately 20% of computed tomography–confirmed burst fractures in the thoracic and lumbar spine appear as wedge fractures on plain film radiography.\(^\text{18}\)
High-dose methylprednisolone is administered as a 30-mg/kg bolus and then as a 5.4-mg/kg/hr infusion for 24 hours (if started within 3 hours of injury) or for 48 hours (if started within 8 hours of injury).
Consider early endotracheal intubation in spinal cord injury patients with a negative inspiratory force of less than −25 cm H₂O or a vital capacity of less than 15 mL/kg.

### CERVICAL SPINE INJURIES

Based on the NEXUS study of 818 patients with cervical spine injury, fractures occurred most commonly at the level of C2 (24% of all fractures), C6 (20%), and C7 (19%). Anatomically, the most commonly fractured part of the cervical spine was the vertebral body, which accounted for 30% of fractures at the C3 to C7 levels. It was more common than fractures of the spinous process (21%), lamina (16%), and articular process (15%). Subluxations occurred most commonly at the C5-C6 (25%) and C6-C7 (23%) levels.\(^\text{19}\)

### THORACIC AND LUMBAR SPINE INJURIES

Similar to patients undergoing cervical spine assessment, low-risk patients may selectively be cleared clinically without radiographic imaging. Although no large studies of thoracic and lumbar spine injuries equivalent to the NEXUS and CCR

| Atlantooccipital dislocation                | Flexion   | Unstable  | 75.7, A| Often instantly fatal
More common in children because of small, horizontally oriented occipital condyles
Dislocation can be anterior (most common), superiorly distracted, or posterior |
| Anterior atlantoaxial dislocation           | Flexion   | Unstable  | 75.7, B| Associated with rupture of the transverse ligament
Most commonly occurs in patients with rheumatoid arthritis and ankylosing spondylitis from ligament laxity
Widening of the predental space seen on lateral plain films |
| Jefferson fracture (C1 burst fracture)      | Axial     | Unstable  | 75.7, C| 33% with associated C2 fracture
Low incidence of neurologic injury because of a wide C1 spinal canal
Usually involves fractures of both the anterior and posterior C1 arches, often with 3 or 4 fracture fragments
Complication: transverse ligament rupture, especially if the C1 lateral masses are ≥7 mm wider than expected (MRI recommended); vertebral artery injury (CT angiography recommended) |
| C1 posterior arch fracture                   | Extension | Stable    | 75.7, C| An associated C2 fracture (occurs 50% of time) makes a posterior arch fracture unstable
On plain films, no displacement of lateral masses on the odontoid view and no prevertebral soft tissue swelling, unlike a Jefferson burst fracture |
| C2 dens fracture                             | Flexion   | Variable  | 75.7, D| Type I (stable): Avulsion of the dens with an intact transverse ligament
Type II (unstable): Fracture at the base of the dens; 10% have an associated rupture of the transverse ligament—MRI provides a definitive diagnosis of ligament rupture
Type III (stable): Fracture of the dens extending into the vertebral body |
| Hangman’s fracture (C2 spondylolisthesis)    | Extension | Unstable  | 75.7, E| Bilateral C2 pedicle fractures
At risk for disruption of the PLL, C2 anterior subluxation, and C2-C3 disk rupture
Low risk for spinal cord injury because of C2 anterior subluxation, which widens the spinal canal |
| Extension teardrop fracture                  | Extension | Unstable  | 75.7, F| Small triangular avulsion of the anteroinferior vertebral body at the insertion point of the ALL
Occurs most frequently at the C2 level but can occur in the lower cervical spine
Complication: central cord syndrome as a result of the ligamentum flavum buckling during hyperextension
Requires CT differentiation from a very unstable flexion teardrop fracture (see “flexion teardrop fracture” in Table 75.7) |

*Listed in progressive order from the occiput, to C1, to C2.

projects have been conducted, recommendations can be extrapolated from the relevant literature.

Based on the NEXUS criteria, patients with (1) significant back pain or tenderness, (2) clinical evidence of drug- or alcohol-related intoxication, (3) lower extremity neurologic deficits, (4) Glasgow Coma Scale score lower than 15, or (5) a distracting injury cannot be cleared clinically for a thoracic or lumbar fracture. Patients with alcohol intoxication, for example, should not be cleared clinically until they are sober and found to fulfill no other high-risk criteria.

Furthermore, based on the CCR criteria and the American Healthcare Research and Quality “red flag” indications for imaging, injured patients who are (1) older than 65 years with any degree of back pain or tenderness, (2) are receiving

chronic corticosteroid therapy, or (3) have a history of vertebral disease should undergo radiography.

Classic patterns of thoracic and lumbar spine injuries are shown in Table 75.8.

**CLASSIFICATION OF SPINAL CORD INJURIES**

**COMPLETE INJURY**
A spinal cord injury is classified as physiologically complete if the patient has no demonstrable motor or sensory function below the level of injury. During the first few days following injury, this diagnosis cannot be made with certainty because of the possibility of concurrent spinal shock.

**INCOMPLETE INJURY**
A spinal cord injury is incomplete if motor function, sensation, or both are partially present below the level of the injury. Signs of an incomplete injury may include (1) the presence of any sensation or voluntary movement in the lower extremities or (2) evidence of sacral sparing. Signs of sacral sparing include perianal sensation, voluntary anal sphincter contraction, and voluntary great toe flexion.

CT, Computed tomography.
Specific incomplete spinal cord injuries include central and anterior cord syndromes, Brown-Séquard syndrome, and conus medullaris syndrome. Patients with these syndromes have certain characteristic patterns of neurologic injury with distinct findings on physical examination.

**CENTRAL CORD SYNDROME**
Central cord syndrome is the most common spinal cord syndrome and is usually due to neck hyperextension. Trauma to the central portion of the cord results in injury to the medially located corticospinal motor tracts of the upper extremities. As a result, the upper extremities are predictably and disproportionately weaker than the lower extremities. Many patients exhibit bladder dysfunction (e.g., urinary retention) and varying degrees of sensory loss. Elderly patients are more at risk for central cord syndrome because of underlying cervical spondylosis, a thickened ligamentum flavum, or both.

**ANTERIOR CORD SYNDROME**
Anterior cord syndrome results from blunt or ischemic injury to the anterior spinal cord. Affected patients have a complete and usually bilateral motor deficit below the level of the injury along with loss of pain and temperature sensation a few levels below the lesion. Typically, posterior column function is preserved.

**BROWN-SÉQUARD SYNDROME**
Brown-Séquard syndrome is a rare hemicord injury that is usually associated with penetrating trauma. Patients have crossed sensory and motor deficits: ipsilateral loss of motor function and position sense below the level of the lesion and contralateral loss of pain and temperature sensation one to two levels below the injury.

**CONUS MEDULLARIS SYNDROME**
Conus medullaris syndrome results from injury to the spinal cord with occasional involvement of the lumbar nerve roots. It results in areflexia of the bladder, bowel, and lower extremities. Patients may exhibit perianal numbness. Motor and sensory deficits in the lower limbs vary.

**CAUDA EQUINA SYNDROME**
Although cauda equina syndrome is not a direct spinal cord injury because the cauda equina is composed entirely of peripheral nerves (lumbar, sacral, and coccygeal nerve roots),
In-line cervical spine immobilization during injury

During the initial resuscitation phase of trauma victims, patients with a potential cervical spine injury may require endotracheal intubation before a definitive diagnosis can be made. By preventing neck hyperextension during direct laryngoscopy, in-line cervical spine immobilization during intubation maintains cervical spine neutrality (Fig. 75.10).

IN-LINE IMMOBILIZATION OF THE CERVICAL SPINE

During the initial resuscitation phase of trauma victims, patients with a potential cervical spine injury may require endotracheal intubation before a definitive diagnosis can be made. By preventing neck hyperextension during direct laryngoscopy, in-line cervical spine immobilization during intubation maintains cervical spine neutrality (Fig. 75.10).

NEUROGENIC SHOCK

Neurogenic shock results from a sympathectomy-induced reduction in blood pressure, heart rate, cardiac contractility, and cardiac output. Overly vigorous fluid resuscitation can be hazardous because of compromised cardiac output. Judicious use of vasopressors such as phenylephrine hydrochloride, dopamine, and norepinephrine is often indicated. Significant bradycardia should be treated hemodynamically with atropine.

Systolic blood pressure lower than 80 mm Hg is rarely due to neurogenic shock alone, and other causes of shock, primarily from hemorrhage, must be excluded. It should never be assumed that hypotension is due to spinal shock until hemorrhage is excluded.

CORTICOSTEROID THERAPY FOR SPINAL CORD INJURY

Though controversial, treatment of blunt spinal cord injury with high-dose methylprednisolone is common. This therapeutic recommendation is based on the findings of the National Acute Spinal Cord Injury Study (NASCIS), which demonstrated improved neurologic function in patients receiving high-dose corticosteroids within 8 hours of injury. Improved neurologic function, however, was defined as a modest gain in motor scores but not functional improvement. In NASCIS, a loading dose of 30 mg/kg of methylprednisolone administered over a 15-minute period was followed by an infusion of 5.4 mg/kg/hr and continued for 24 hours (in patients treated within 3 hours of injury) or 48 hours (in patients treated 3 to 8 hours after injury).20,21 No benefit was found when steroids were administered more than 8 hours after injury.

Steroid therapy is not indicated for penetrating injuries and has not been adequately studied in children younger than 13 years or in patients with cauda equina or spinal root injury.

Finally, systemic corticosteroid therapy is not benign. Complications of steroid therapy include gastrointestinal hemorrhage and wound infection in patients treated with corticosteroid infusions for 24 hours and higher rates of severe sepsis and severe pneumonia in those treated for 48 hours. The use of steroids for blunt traumatic spinal cord injury is far from the standard of care.22 More research is needed to verify or refute this controversial therapy.

SURGICAL MANAGEMENT OF SPINAL CORD INJURY

Timely reduction of the displaced spinal column plus decompression of the spinal cord has been associated with recovery from otherwise devastating spinal cord injuries.23 The optimal timing of surgery following a spinal injury remains controversial. Some argue for immediate surgery, whereas others advocate delayed surgery because of the initial post-traumatic swelling. The sole absolute indication for immediate surgery is progressively worsening neurologic status in patients with spinal fracture-dislocations who initially have incomplete or absent neurologic deficits.24
In a series of patients with traumatic central cord syndrome, those who underwent early surgery (<24 hours after injury) and had an underlying disk herniation or fracture-dislocation exhibited significantly greater overall motor improvement than did those who underwent late surgery (>24 hours after injury). 22 Unfortunately, early decompressive surgery does not uniformly improve outcome following spinal cord injury.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Most patients with traumatic spinal fractures are admitted to the hospital because they fulfill at least one of four admission criteria: (1) intractable pain, (2) fracture involvement of more than one column, (3) a functionally unstable fracture pattern, and (4) the presence or potential for development of a spinal cord injury.

Patients who can be discharged home include those with normal neurologic function and (1) an isolated, stable posterior column fracture (spinous process, transverse process) in the cervical, thoracic, or lumbar spine or (2) a stable wedge fracture in the thoracic or lumbar spine.

Patients with confirmed or suspected spinal cord injury should be scheduled for early consultation with a neurosurgeon or orthopedist. This may require transfer of the patient to a spine specialty center.

The level of the spinal cord injury, associated neurologic deficits, and other traumatic injuries will determine whether the patient should be admitted to the intensive care unit, neurosurgical observation unit, or general ward. Circular beds, rotating frames, and serial inflation devices are used to protect the patient from pressure sores.

Discharged patients without a fracture or spinal cord injury require only conservative management. Discharged patients with a stable spinal fracture require only conservative management with or without an immobilization device, such as a cervical collar or thoracolumbar sacral orthosis back brace. Soft collars and back braces are not recommended because they predispose patients to stiffness of the neck and back, respectively.

Discharged patients with persistent neck pain who are still at risk for an unstable ligamentous injury should wear a semi-rigid cervical collar (e.g., Philadelphia or Miami J collar) for 7 to 10 days until adequate flexion-extension plain films can be obtained. Discharge instructions should include information about the warning signs of spinal cord injury.

• Provide pain control.
  Maintain full spinal precautions until the spine can be cleared radiographically or clinically.
  If intubating a trauma patient, an assistant should provide in-line cervical spine immobilization until the cervical spine can be assessed more definitively at a later time.
  Perform a careful initial neurologic examination, especially in patients who are about to undergo sedation or neuromuscular blockade.

If a spinal fracture is suspected or detected, evaluate for associated injuries:
• For the cervical spine, examine for associated head and facial injuries.
• For the thoracic spine, examine for rib fractures and pulmonary, cardiac, diaphragmatic, and mediastinal injuries.
• For the lumbar spine, examine for intraabdominal injuries, pelvic fractures, and calcaneal fractures.
• For all spinal levels, examine for spinal cord injury.

Obtain urgent spine imaging if a fracture or spinal cord injury is suspected.
Obtain emergency magnetic resonance imaging of the spine if a spinal cord injury is suspected.
Consider administering corticosteroids if an adult patient has sustained blunt spinal trauma and exhibits neurologic deficits within 8 hours of injury.

Prolonged immobilization on a rigid backboard is uncomfortable for the patient and places the patient at risk for aspiration and early pressure sores. Aim to remove the backboard as soon as possible and ideally within 2 hours of patient arrival. A standard hospital gurney provides adequate thoracic and lumbar stability.

Perform serial neurologic examinations on patients with suspected or known spinal injuries to document neurologic improvement or deterioration. Neurologic deterioration involving the cervical and upper thoracic levels may require empiric endotracheal intubation for impending respiratory failure.

Once a spinal injury is detected, carefully reexamine the entire cervical, thoracic, and lumbar spine. Obtain plain films or computed tomography scans of any levels with pain or tenderness because of the high risk for a second spinal injury.

When performing “clinical clearance” of a patient’s cervical spine or obtaining flexion-extension cervical spine plain films, do not passively range the neck for the patient. This may cause an iatrogenic spinal injury. Pain with active movement will prevent the patient from overranging the neck.

Document neck and back tenderness, along with the neurologic examination, in all trauma patients.
In spinal cord injury patients, mark the initial level of sensory deficit to monitor progression of the patient’s neurologic status.
For patients with neurologic deficits, perform and document the bulbocavernosus reflex and sacral-sparing examination to assess for spinal shock.

Facial Trauma

John H. Burton and Karen Nolan Kuehl

The major bones of the face create the defining features and include the frontal, nasal, zygoma, maxilla, mandible, and temporal bones. The orbit consists of the maxilla, zygoma, frontal, sphenoid, orbital, and lacrimal bones (Fig. 76.1).

The face is conventionally divided into thirds: upper, middle, and lower. The borders of each third are loosely defined by branches of the trigeminal nerve, which provides sensory innervation to the face. Identification of the exiting foramen for the distributing branches of the trigeminal nerve (cranial nerve V) is crucial when providing local nerve anesthesia (Fig. 76.2).

The facial nerve (cranial nerve VII) intricately courses through the parotid duct and provides parasympathetic innervation, special sensory function to the tongue and soft palate, and general motor function to the 44 muscles of facial expression. Deep facial lacerations between the tragus and lateral canthus may jeopardize the integrity of the facial nerve. Any damage to the facial nerve distal to the stylomastoid foramen can result in facial nerve dysfunction, commonly referred to as Bell palsy.

The parotid duct lies in a plane with the tragus and inferior corner of the nasal vestibule. Competency of the parotid duct must be considered in patients with deep lacerations in this region of the face (Fig. 76.3).9

The external carotid artery is the major vascular supply to the face. This vessel provides extensive collateral supply to the midline tissues through anastomosis (Fig. 76.4).10

**APPROACH TO MULTITRAUMA PATIENTS WITH FACIAL INJURIES**

The degree of tissue distortion following facial trauma should not dissuade the EP from addressing the initial treatment priorities in patients. Though uncommon, facial trauma can be a life-threatening insult, and the EP must address life-threatening injuries before evaluating the obvious facial injury. The mere presence of a facial fracture, particularly one involving the midface, greatly increases the risk for traumatic brain injury.11,12 The energy required to fracture the midface is often transmitted to the neurocranium, and such fractures are associated with a high incidence of brain death. In general, patients with facial fractures who do not survive have higher injury severity scores and lower Glasgow Coma Scale scores and consist of an older population. Other typical concomitant injuries include pulmonary contusions, abdominal injuries, and cervical spine injuries.13 The emergence of motor vehicle air bags has decreased patient mortality. However, increased concern is warranted for injuries to the orbits, globes, facial

**KEY POINTS**

- Treatment of all facial injuries should initially be directed toward maintaining the airway and stabilizing life-threatening injuries.
- Facial computed tomography is routinely performed to visualize facial fractures; however, plain radiographs may be sufficient in patients with isolated facial injury and a low index of suspicion for a midface fracture or concomitant intracranial injuries.

**PERSPECTIVE**

A person’s face is the focal point of conversation and social interaction. Within the face is embodied each person’s mode of expression and communication. The face also has a receptive importance, with many special sensory functions of the body located within the facial structures. It is not surprising that facial disfigurement harbors the potential for both physical impairment and long-term psychologic sequelae.1,2

Death from facial trauma is rare, and the severity of facial injuries is often perceived by the patient to be out of proportion to the actual injury. The goal of the emergency physician (EP) is to secure the airway, identify the injury, preserve appearance, and consult with the appropriate surgeon to determine further treatment and follow-up.3 Although zygomatic and nasal fractures may occur in isolation, any fracture of the frontal bone and maxilla must raise suspicion for the possibility of associated facial fractures, intracranial injury, and concomitant cervical spine injury.4,5 Proper diagnosis and recognition of zygoma and nasal pathology are essential for maintenance of adequate cosmetic and physiologic function. Trauma involving the mandible, the strongest facial bone, may result in fracture or dislocation. Fifty percent of mandibular fractures occur at two or more locations because of its pseudo-ring shape. Detection of one fracture site should always prompt a search for a second fracture.6

**GENERAL ANATOMY**

The major bones of the face create the defining features and include the frontal, nasal, zygoma, maxilla, mandible, and temporal bones. The orbit consists of the maxilla, zygoma, frontal, sphenoid, orbital, and lacrimal bones (Fig. 76.1).
Treatment of bleeding must begin with inspection of the airway and maintenance of its patency. Local hemorrhage may be controlled with posterior nasal packing or insertion of a Foley catheter into the nasopharynx and inflation with air. The catheter should be gently pulled anteriorly in an attempt to close the posterior choana. Temporary external reduction of fractures may also provide stabilization of arterial injuries. Finally, surgical ligation of the external carotid artery or transcatheter arterial embolization of the maxillary artery can be

soft tissues, and temporomandibular joints, as well as cervical fractures of the posterior arches of C1 and C2.

The blood supply to the face consists of a complex system involving branches of the internal and external carotid arteries with several anastomoses between them. The majority of the facial vascular supply is via the internal maxillary artery, which originates from the external carotid. The internal maxillary artery passes between the Le Fort fracture lines and can be dissected with severe midface trauma.

**Fig. 76.1** Facial bones and essential structures of the facial anatomy.
strikes the dashboard or steering wheel. Assault with a blunt object is also a common injury mechanism.

**ANATOMY**

The frontal bone is the only constituent of the forehead; the prominent protuberance is called the glabella. Within the frontal bone resides the frontal sinus, which communicates with the nasopharynx via the frontonasal canal. The anterior bone of the frontal sinus is thicker than the posterior aspect. The intracranial dura mater is adherent to the posterior frontal sinus wall. Cutaneous innervation of the frontal bone is supplied by the superior orbital nerve, a branch of the trigeminal nerve.

**TREATMENT**

Frontal sinus fractures are usually diagnosed by computed tomography (CT). Displaced anterior wall fractures require either immediate repair or delayed reconstruction. Conversely, frontal bone fractures that involve the posterior wall of the sinus are associated with cerebrospinal fluid (CSF) rhinorrhea; the patient will require urgent consultation with a neurosurgeon and admission to the hospital. Ocular trauma or sudden loss of vision associated with a frontal bone injury requires immediate ophthalmologic consultation.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Anterior frontal sinus fractures without any concomitant injuries are not life-threatening; the patient can be discharged with close consultant follow-up to maintain an adequate cosmetic result. Although antibiotics have not been shown to decrease the incidence of meningitis associated with a CSF leak and frontal bone fracture, antibiotic therapy should be based on the consultant’s preference.
BLUNT OPHTHALMIC AND ORBITAL TRAUMA

PATHOPHYSIOLOGY

Trauma to the eye can result from falls, motor vehicle accidents, and direct blows from an assault or a projectile object (hockey puck, baseball). Serious eye injury has been shown to most commonly be associated with midface fractures.\(^{17,18}\)

Ocular trauma can be divided into two broad categories: direct trauma to the globe and trauma to the orbit. Direct globe trauma ranges in severity from a benign corneal abrasion to rupture of the globe. Orbital trauma involves injuries such as benign contusions and fractures with complications to surrounding structures, including the globe and extraocular muscles.

Orbital fractures are classified as “impure” when the fracture line involves the orbital rim or as “pure” in the case of a fracture with no rim involvement. Compression of the optic nerve (ocular neuropathy) can be caused by displacement of a fracture, increased pressure from a retrobulbar hemorrhage, or optic nerve hemorrhage.\(^{19}\) Each of these processes has the potential to lead to rapidly progressive visual loss and is an ophthalmologic emergency.

The mechanism of orbital blowout fractures was investigated by Waterhouse et al. via the same principles as Le Fort a century earlier (see later).\(^{20}\) Waterhouse investigated the two possible mechanisms for an orbital blowout fracture, the hydraulic and buckling theories. The hydraulic mechanism occurs when the vector of the force directed onto an uninjured globe is transmitted to the fixed orbital walls; it results in a large fracture of the inferior or medial orbital wall, or both (Fig. 76.5). This mechanism is commonly associated with herniation of the orbital contents through the fractured orbital wall, hence the term blowout. The buckling mechanism, in contrast, occurs when a traumatic force is directed to the inferior orbital rim and causes only the inferior floor of the orbit to buckle, or fracture, with no associated herniation of the orbital contents.
Herniation of the orbital contents—fatty connective tissue, inferior rectus, and inferior oblique muscles—occurs at the weakest portions of the orbit, specifically, the orbital floor and the anteromedial wall. With increased pressure on the globe, any defect in these bony structures may lead to herniation of the orbital contents and resultant muscular entrapment.

ANATOMY

The globe resides within a cone-shaped socket composed of seven bones of varying thickness. The thinnest bony portion of the socket is the orbital floor. The globe is protected from trauma by the thick superior rim of the frontal bone and the inferior rim of both the maxilla and zygoma. The orbital rim possesses a smooth contour with occasional notching that is symmetric when encountered. Any asymmetric step-off of this rim is indicative of a potential rim fracture.

The eye is cushioned by a retrobulbar fat pad encasing the globe. The extraocular muscles complete the orbital anatomy by surrounding the globe and enabling eye movement. Herniation of any orbital contents through the inferior or medial walls will result in protrusion of these structures, in whole or in part, into the maxillary or ethmoidal sinus, respectively. The inferior rectus and inferior oblique muscles, both innervated by cranial nerve III, lie adjacent to the inferior and medial orbital floors and are the most commonly affected extraocular muscles with a blowout injury.

PRESENTING SIGNS AND SYMPTOMS

Patients with a history of facial trauma should undergo complete evaluation of the eye and the encasing orbit. Initial inspection may reveal periorbital ecchymosis and edema, discrepancy in eye level, or enophthalmos. Enophthalmos is consistent with an orbital blowout fracture. 

• Binocular diplopia (blurring of vision when both eyes are open) is indicative of an ocular muscle imbalance between the two eyes as a consequence of muscle entrapment, contusion, or displacement of the globe secondary to edema from surrounding structures.
• Monocular diplopia (blurring of vision when only one eye is open) is often indicative of lens dislocation, hyphema, or partial globe rupture.
• Flashing lights, or floaters, can be consistent with a retinal tear, retinal detachment, or vitreous hemorrhage.
• Any loss of perception of light or identification of colors or the presence of central scotomata without association with pain is indicative of optic neuropathy. Absence of light perception following an orbital fracture is a poor prognostic indicator for recovery of vision.
• Rapid loss of vision in one eye associated with edema, proptosis, and tension on palpation should heighten suspicion for the presence of a retrobulbar hematoma.
• Pain with eye movement is commonly associated with an orbital fracture.

The eye examination should begin with palpation of the orbital rims. The rims should be evaluated for crepitus, a step-off deformity, subcutaneous emphysema, and decreased sensation in the distribution of the inferior and superior orbital nerves.

Pupil size, shape, and light reflex must be examined to assess optic nerve status. Full ocular muscle function is evaluated by slow, directed passive range of motion. Upward gaze palsy with vertical diplopia is consistent with dysfunction of the inferior rectus muscle and suggests entrapment from an orbital blowout fracture. Enophthalmos is common when a large amount of tissue herniates through an orbital floor defect into the adjacent maxillary sinus.

The EP must evaluate both eyes for visual acuity. This examination may be facilitated by using a Snellen eye chart or pocket card or by asking the patient to read the text of a newspaper or other print. Visual impairment should prompt immediate consultation for the suspected injury. If the patient’s injury allows proper positioning and cooperation, a slit-lamp examination is warranted to fully evaluate the conjunctiva, lens, iris, sclera, cornea, and anterior chamber of the globe. Intraocular pressure can be measured. However, if the globe has possibly been ruptured, intraocular pressure assessment should be deferred to an ophthalmologist.

DIAGNOSTIC CRITERIA AND TESTING

If the pretest probability of orbital or ocular damage is low or if CT is not available, a Waters view radiograph of the midface is a screening tool for fracture or resultant blood in the sinus, subcutaneous emphysema, depression of the bony fragments, or the “hanging teardrop” sign whereby herniated globe structures may be visualized in the maxillary sinus roof. If suspicion of orbital or ocular injury is high, particularly when concomitant intracranial or facial injuries are suspected, CT is required to elucidate the extent of the identified injury. This examination should include views of the head, as well as axial and coronal cuts of the midface and orbits.

TREATMENT

Management of blowout fractures is complicated. The presence of an orbital fracture with findings of herniation on clinical or radiographic examination requires immediate surgical consultation to guide the treatment plan. Immediate indications for surgical intervention include muscular entrapment with gaze restriction or acute enophthalmos. Contraindications to surgery include globe rupture, hyphema, and retinal tears. These injuries should prompt emergency ophthalmologic consultation. An ophthalmologist should also be contacted for patients with evidence of lens dislocation, laceration of the cornea or sclera, or rapid loss of visual acuity.

Patients with an isolated blowout fracture may be discharged home with follow-up arranged within 2 weeks to assess for resolution of the swelling. If entrapment is present at follow-up, the patient would require open reduction of the fracture. Even patients with a blowout fracture may have their symptoms improve over a 10-day to 2-week period and may not require surgical intervention.
An increase in retrobulbar pressure from a hematoma or emphysema can lead to acute and permanent loss of vision. Lateral canthotomy can be a vision-saving intervention in this context. This simple procedure is intended to relieve pressure on the optic nerve and, ultimately, preserve the patient’s vision through resolution of the optic nerve traction and ischemia. Immediate ophthalmologic consultation should be obtained to perform the lateral canthotomy; when a consultant is unavailable or if a lengthy response time is anticipated, the procedure should be undertaken by the EP.

Local anesthetic without epinephrine is injected into the lateral canthus. An incision is made in the canthus with a pair of fine, sharp scissors. The incision is made in the canthus at the juncture of the upper and lower eyelids between the globe and the orbital rim. Expulsion and drainage of the hematoma should ensue through the incision site.

**ZYGOMA INJURY**

**PATHOPHYSIOLOGY**

Zygoma fractures are the result of an anterolateral force applied to the midface by falls, deceleration injuries, or assault by blunt objects, including a fist. The zygoma is a thick bone. A direct blow to the zygoma may not necessarily result in a fracture but instead may transmit the force to adjacent weaker areas of the orbit and maxilla and cause a complex fracture. Inward and downward displacement of the zygoma in relation to its articulating surfaces results in the classic zygomaticomaxillary complex fracture, also called a tripod or malar fracture (Fig. 76.6). Communal fractures of the zygoma are associated with penetrating trauma, such as gunshot wounds.

**ANATOMY**

The term *zygoma* is derived from the Greek word *zygon*, meaning a yoke or crossbar by which two draft animals are hitched to a plow. The zygoma forms the lateral buttress of the face, inferior and lateral orbital rim, and a portion of the orbital floor. Thus a zygoma fracture, by definition, is an orbital floor fracture.

The zygoma articulates with four bones: the maxilla, temporal bone, frontal bone, and greater wing of the sphenoid. For this reason, a zygomaticomaxillary complex fracture—typically referred to as a tripod fracture—is technically a misnomer.

The zygoma forms part of the superior and lateral aspect of the maxillary sinus, and disruption may lead to subcutaneous air. Numerous muscles attach to the zygoma, the most prominent being the masseter, which consequently results in inward and downward displacement of a zygomaticomaxillary complex fracture and trismus.

**PRESENTING SIGNS AND SYMPTOMS**

Common symptoms with fracture of the zygoma include the following:

- Pain over the affected area
- Difficulty opening the jaw secondary to the origin of the masseter (trismus)
- Paresthesia in the distribution of the inferior orbital nerve (Fig. 76.7)
- Binocular diplopia as a result of entrapment of intraocular muscles

The initial physical examination typically reveals severe edema of the zygoma area with possible inferior displacement of the lateral canthus, periorbital edema, and subconjunctival hemorrhage. The face should be evaluated from the superior and inferior aspects to discern any flattening of the cheek.
relative to the contralateral side. The zygoma should be palpated for evidence of a step-off of the inferior orbital rim, crepitus of the zygoma, or subcutaneous emphysema.

Intraoral examination of the zygoma is accomplished by placing a gloved finger along the superior and lateral aspect of the maxillary molars. If this area is tender or if the finger is unable to pass under the arch, a fracture of the zygoma is likely.

A complete ocular examination should be performed to evaluate for entrapment of muscles and possible orbital fracture. Ten percent to 20% of zygoma injuries will be associated with ocular injury.

**DIAGNOSTIC CRITERIA AND TESTING**

If a nondisplaced, isolated zygoma fracture is suspected, a “jug-handle,” submentovertex plain radiographic view may be sufficient for diagnosis. Otherwise, a Waters view constitutes an adequate screening radiographic study for a more complicated fracture. If the Waters view reveals a zygomaticomaxillary complex fracture or if ocular muscle entrapment is suspected, facial CT scans are required for more complete evaluation of the injury.

**TREATMENT**

Initial management of patients with zygomaticomaxillary complex fractures should include prompt diagnosis and exclusion of ocular muscle entrapment or intracranial injuries. If subcutaneous emphysema is present, antibiotics should be initiated immediately; amoxicillin is an effective first-line agent.23

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with an isolated arch fracture can be discharged with appropriate follow-up. However, patients with greater than 2-mm displacement will typically require open reduction. In contrast, patients with a zygomaticomaxillary complex fracture, any injury with impairment of vision, or substantial concomitant injuries will require admission to the hospital with surgical consultation for consideration of open reduction and internal fixation.

**MAXILLARY AND MIDFACE INJURIES**

**PATHOPHYSIOLOGY**

**LE FORT CLASSIFICATION**

Maxillary fractures resulting from severe blows to the head have traditionally been classified according to the Le Fort classification scheme established by René Le Fort in 1901. Le Fort was a French surgeon who induced trauma in 35 cadaveric heads by striking them with a bat or smashing them against a table edge. Next, Le Fort boiled the heads to remove the soft tissue and documented the fracture lines. In his classic treatise on the subject, Le Fort illustrated three predictable midface fracture lines. These injuries rarely occur in isolation, but they are often used as a reference to describe maxillary trauma (Fig. 76.8).

**Le Fort I (Transverse)**

This midface fracture is the result of lateral force applied to the face. The Le Fort I fracture line extends horizontally above the roots of the teeth and involves only the maxilla. A step-off deformity of the upper palate will be present (if not complete). Rocking of the teeth will lead to motion of the midface, with a sensation similar to that of a loose denture.

**Le Fort II (Pyramidal)**

This injury is the result of extreme force directed to the nose and midface and results in separation of the midface from its articulating structures. The Le Fort II fracture line extends through the inferior orbital rim and over the nasal ridge and separates the upper palate and nose from the remainder of the face.

**Le Fort III (Craniofacial Disjunction)**

A Le Fort III is the most severe type of facial fracture. The facial fracture line is horizontal and extends through the nasal bone and laterally through the orbits. This injury results in separation of the facial bones from the base of the skull.

**ANATOMY**

The maxilla is primarily innervated by the inferior alveolar nerve, which emerges from the inferior orbital foramen. Clues to evidence of a midface fracture may include paresthesias in the region of the inferior alveolar nerve.

The nose is a highly vascularized structure within the maxilla. Severe epistaxis associated with a maxillary injury can lead to airway obstruction. Therefore, hemostasis is essential in the approach to maxillary injuries.
Examination of the midface for instability.24 manipulation of the midface offers little benefit and may cause liable. If a fracture is highly suspected or if CT is planned,ments have a high false-positive rate and are considered unre-

tents may be undertaken; however, both these assess-

The EP should place one hand on the patient’s forehead to stabilize the head while grasping the upper palate by the anterior teeth with the other hand. Gentle back-and-forth pressure should be applied while palpating the midface for movement (Fig. 76.9). If motion of the midface structures is detected with this technique, further classification of the extent of the injury should be performed by localization of the nasal ridge or inferior orbital rims with the other hand. If CSF rhinorrhea is suspected, testing the fluid for glucose or the halo sign may be undertaken; however, both these assessments have a high false-positive rate and are considered unreliable. If a fracture is highly suspected or if CT is planned, manipulation of the midface offers little benefit and may cause increased bleeding.24

Initial evaluation of a patient with a maxillary injury depends on its severity; findings include severe edema, malocclusion, periorbital ecchymosis, facial asymmetry, a long or “donkey” face, and enophthalmos. Palpation of the maxillary structures may reveal crepitus and abnormal mobility of the structures. Anesthesia over the cheek implies disruption of the inferior orbital nerve.

Airway obstruction is often secondary to uncontrolled bleeding. Therefore, attempts at hemostasis should be undertaken early in the evaluation. Assessment of facial fracture bleeding should be completed during the “circulation” component of the ABCDE (airway, breathing, circulation, disability, exposure) evaluation technique advocated by the advanced trauma life support protocol. Early oral endotracheal intubation may be required and allows more aggressive control of bleeding.

Nasopharyngeal intubation should be avoided with midface injuries. A surgical airway (e.g., cricothyrotomy) may be necessary because of anatomic damage or excessive bleeding. Placement of an orogastric tube will allow assessment of swallowed blood, which can provide valuable information in a multitrauma patient with developing tachycardia, hypotension, or both.

If hemostasis of the nares cannot be achieved, a Foley catheter should be carefully advanced into the nasopharynx and inflated with air (overinflation may result in septal necrosis). The catheter should be gently pulled anteriorly in an attempt to close the posterior choana. Once the catheter is in place, the nasal cavity can be packed with gauze or nasal tampons for control of anterior epistaxis. The physician must be careful when advancing any tube through the nares because violation of the anterior cranial base can allow passage of the catheter into the cranium. If bleeding is not controlled with Foley catheters and packing, embolization of bleeding vessels with possible surgical exploration and ligation of vessels should occur. Emergency consultation with ear, nose, and throat (ENT), plastic surgery, and interventional radiology services should be considered early if the patient requires angiography. Regardless of the severity of bleeding, all patients with facial fractures should be reevaluated for hemorrhage every 30 minutes for a period of up to 6 hours.25

In patients with a high index of suspicion for a facial fracture, neurologic deficit, or severe facial distortion or in those who are undergoing CT evaluation for any reason other than midface trauma, CT of the facial bones with fine axial and coronal cuts should be the initial imaging study.

If no other significant injuries are present and the findings on clinical examination are ambiguous for a facial fracture, a Waters plain radiographic facial view is an excellent screening examination. If plain radiography reveals an obvious fracture or opacification of a maxillary sinus, CT is warranted and should be performed in follow-up or at the time of the initial encounter, as dictated by the needs of the patient and preference of the surgical consultant.

Before a thorough evaluation of the maxilla is undertaken, the EP must first stabilize the patient and ensure that the airway is preserved. Airway compromise is more common with Le Fort II and III fractures but may also be seen with Le Fort I injuries.

Airway obstruction is often secondary to uncontrolled bleeding. Therefore, attempts at hemostasis should be undertaken early in the evaluation. Assessment of facial fracture bleeding should be completed during the “circulation” component of the ABCDE (airway, breathing, circulation, disability, exposure) evaluation technique advocated by the advanced trauma life support protocol. Early oral endotracheal intubation may be required and allows more aggressive control of bleeding.

Nasopharyngeal intubation should be avoided with midface injuries. A surgical airway (e.g., cricothyrotomy) may be necessary because of anatomic damage or excessive bleeding. Placement of an orogastric tube will allow assessment of swallowed blood, which can provide valuable information in a multitrauma patient with developing tachycardia, hypotension, or both.

If hemostasis of the nares cannot be achieved, a Foley catheter should be carefully advanced into the nasopharynx and inflated with air (overinflation may result in septal necrosis). The catheter should be gently pulled anteriorly in an attempt to close the posterior choana. Once the catheter is in place, the nasal cavity can be packed with gauze or nasal tampons for control of anterior epistaxis. The physician must be careful when advancing any tube through the nares because violation of the anterior cranial base can allow passage of the catheter into the cranium. If bleeding is not controlled with Foley catheters and packing, embolization of bleeding vessels with possible surgical exploration and ligation of vessels should occur. Emergency consultation with ear, nose, and throat (ENT), plastic surgery, and interventional radiology services should be considered early if the patient requires angiography. Regardless of the severity of bleeding, all patients with facial fractures should be reevaluated for hemorrhage every 30 minutes for a period of up to 6 hours.25

Antibiotic prophylaxis for basilar skull fractures has not been shown to decrease the risk for meningitis.26 However, prophylactic antibiotic regimens may still be used in an attempt to prevent translocation of mouth and sinus flora.27

Evidence of a basilar skull fracture or pneumocephalus requires prompt neurosurgical consultation. Maxillary fractures often require surgical repair to restore normal occlusion and facial stabilization, and thus consultation and follow-up with an oromaxillofacial or plastic surgeon is important. Patients with demonstrated or suspected Le Fort II or Le Fort III injuries require hospital admission for stabilization and management.
NASAL INJURIES

PATHOPHYSIOLOGY

Nasal bone fractures are commonly the result of sports-related trauma, assault, and motor vehicle crashes. The force required to fracture the nasal bone ranges from 16 to 66 kPa, the least of any facial bone. Simple deviated nasal fractures are the result of a lateral force against the nasal prominence. More complex nasoorbitoethmoid fractures are due to a stronger force directed toward the bridge of the nose with displacement of the bone segments posteriorly. This type of fracture is frequently associated with other facial and brain injuries.

ANATOMY

The nasal bone consists of two small wedge-shape bones that are fused in the midline and protrude from the frontal process of the maxilla laterally and frontal bone superiorly. The upper portion of this paired structure is significantly thicker than the lower segments, thereby leading more commonly to fractures of the latter. The external nose is composed of cartilaginous and fatty tissue and has an intricate blood supply from distal branches of the internal and external carotid arteries.

PRESENTING SIGNS AND SYMPTOMS

Patients with nasal trauma have complaints of tenderness, edema, epistaxis, and periorbital ecchymosis. Palpation of the area can reveal crepitus, hypermobility, and deformity of the nasal septum.

DIAGNOSTIC CRITERIA AND TESTING

Plain radiography is of limited value in patients with simple nasal trauma and has no clinical implication in management. Patients can be reassured that radiographs may be obtained at follow-up if any cosmetic deformity persists and surgical repair is required. If the physician is concerned that a nasoorbitoethmoid fracture is present, axial and coronal CT of the face is necessary.

TREATMENT

The EP should not attempt reduction of closed nasal fractures. Given the extensive edema that generally ensues before the patient arrives at the emergency department (ED), the EP will be unable to approximate realignment of the nasal septum. Epistaxis should be dealt with during the clinical evaluation. Analgesia should be adequately addressed during the patient’s visit and at follow-up.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients with known or suspected nasal fractures or septal displacement should be referred to an otolaryngologist or...
plastic surgeon within 1 week of their injury for reevaluation and planning of management. Patients may also be educated that if no deformity is apparent after the swelling has subsided, ENT follow-up is unnecessary. Children with nasal fractures should be seen in follow-up within 4 days because of rapid bone healing. Patients should be instructed to avoid blowing their nose given that subcutaneous emphysema may ensue as a result of displacement of air across the injured nasal structures.

Emergency consultation for consideration of nasal reduction is indicated if the nasal pyramid is deviated greater than half the width of the nasal bridge or if an open septal fracture has occurred. Open nasal fractures require immediate attention because cartilage necrosis may ensue if the exposed cartilage is not covered within 24 hours. Nasoorbitoethmoid fractures require a multidisciplinary approach, including oromaxillofacial, plastic, and neurosurgical consultation.

If a septal hematoma is identified, immediate evacuation is required. The nasal passage on the affected side is prepared via topical anesthesia and injection of lidocaine into the anterior septum. The hematoma is initially drained with a large-bore needle at the inferior aspect. The needle track is then enlarged with a No. 15 surgical blade. Next, the anterior nares are tightly packed bilaterally in an attempt to reappose the septal mucosa. Patients with septal hematoma should routinely be prescribed a course of antibiotics and otolaryngologic follow-up arranged within 4 days to assess the injury for evidence of reaccumulation of the hematoma. On discharge, patients need to be educated that any reaccumulation of septal hematoma will require emergency reevacuation. In addition, these patients need to be educated to avoid blowing their nose.

LOWER FACE INJURIES

PATHOPHYSIOLOGY

The location of mandibular fractures has some correlation to the insult received. High-velocity forces directed to the chin result in symphysis or condylar fractures (or both), and a high proportion of these injuries result in comminuted fractures. In contrast, assault-related injuries are more commonly associated with fractures of the angle and ramus. The location of trauma impact does not necessarily correlate with the location of the fracture site because the force of the impact can be transmitted to a distant area.

Dislocations of the mandible can be due to trauma, excessive mouth opening (yawning), seizure, or a dystonic reaction from medication. The mandible dislocates anteriorly and then superiorly, with spasm of the jaw muscles preventing realignment. Unilateral dislocation causes deviation of the mandible away from the affected side. Bilateral dislocation results in an open jaw and underbite appearance.

ANATOMY

The mandible is a horseshoe-shaped bone and appears similar to the letter L from a lateral view (Fig. 76.11). It has 16 tooth sockets innervated by the inferior alveolar nerve. The mandible articulates with the temporal bone bilaterally via a ginglymoarthrodial (hinge and sliding) joint to form the temporomandibular joint. The arterial supply to the mandible is via branches of the maxillary artery.
The temporomandibular joint consists of the mandibular condyle process and the mandibular fossa of the temporal bone interspaced with a cartilaginous disk and surrounded by a joint capsule. If the jaw is opened slightly, the hinge action predominates as the condylar process rotates within the socket. However, as the jaw is opened wider, the mandibular condyles glide forward to the articular tubercle of the temporal bone. Overextension of the joint results in anterior dislocation of the mandibular condyle process and subsequent spasm in the masseter and pterygoid muscles, which prevents normal mouth closure.

**PRESENTING SIGNS AND SYMPTOMS**

Typical initial symptoms of a mandibular injury include mandibular pain, abnormal jaw motion, malocclusion, and paresthesia of the ipsilateral lower lip secondary to disruption of the mandibular nerve. Patients often state that their "bite is off," a sign of displacement or malocclusion of the mandible or maxilla. If the patient reports pain in the preauricular area, fracture of the condyle is frequently present.

Examination of the mandible should begin with visual inspection for edema, deviation with passive range of motion, and a "widened face," an indication of a bilateral condylar fracture. The EP should palpate the outside of the face to ensure preservation of the smooth contour of the mandible. During the intraoral examination, clues to a mandibular fracture include ecchymosis of the floor of the mouth and mucosal tears. Any obvious separation of the lower teeth or step deformity is pathognomonic for fracture.

The EP inspects the temporomandibular joint by first performing an otoscopic examination for signs of perforation of the external ear canal or hemotympanum. A Battle sign is indicative of perforation of the glenoid fossa by a fractured condyle. Next, the examiner’s fingers are placed in the external canal, and the patient is instructed to open and close the mouth. Tenderness or crepitus elicited with this examination is indicative of a condylar fracture.

If the clinical findings are misleading, one can perform the tongue blade test, which has been demonstrated by Alonso and Purcell to have high sensitivity in screening for mandibular fractures. The test is performed by placing a wooden tongue blade between the molars (Fig. 76.12). The patient is instructed to bite down, and the examiner exerts a twisting motion in an effort to crack the wooden blade between the patient’s teeth. If the EP is unable to crack the blade between the patient’s teeth during the twisting motion—because of pain or malocclusion—a positive test is confirmed with subsequent enhanced suspicion for a mandibular fracture.

**DIAGNOSTIC CRITERIA AND TESTING**

Initial radiographs should include lateral and posteroanterior views and a Towne view of the mandible (if Panorex is unavailable). If the index of suspicion for a condylar fracture is high despite normal radiographic findings, CT with fine cuts of the condyle will be necessary to definitively rule out a fracture. If evidence of an avulsed tooth is present on clinical examination, a chest radiograph should be obtained to evaluate for aspiration.

**TREATMENT**

Initial management of a mandibular fracture should ensure that the patient can maintain a patent airway without difficulty. Pain relief may then be obtained with nonsteroidal antiinflammatory drugs and narcotic agents. Because of the potential for wound infection from mouth flora, patients with open mandibular fractures should be treated with oral or intravenous penicillin. Clindamycin is an excellent choice for penicillin-allergic patients. Stabilization of a displaced mandibular fracture can be achieved with a Barton bandage.

When traumatic temporomandibular joint dislocation is encountered, the EP must obtain a dental panoramic study to consider the presence of a concomitant condylar fracture. If no indication of fracture is present, an attempt at reduction of the mandible in the ED may be undertaken with provision of intravenous benzodiazepines, as well as occasional procedural sedation and analgesia, to relax the muscles of mastication.

To perform reduction, the EP’s thumbs are wrapped in gauze (to prevent injury). The EP faces the patient and places the thumbs on the posterior molars of the patient’s mandible; the remaining fingers are wrapped around the inferior border of the mandible. Force is directed down on the thumbs as the symphyseal area is raised toward the EP. If reduction is unsuccessful, the patient may require general anesthesia. After reduction of an acute dislocation, the patient should be placed on a soft diet and instructed not to open the mouth wide for 7 days.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Any patient with an open or unstable mandibular fracture requires admission for occlusion fixation or mandibular wiring. Patients with stable fractures may be discharged home and instructed to maintain a soft diet, and prompt outpatient follow-up should be arranged with an otolaryngologist or oral surgeon. Edentulous patients usually require admission to the hospital and internal fixation because they do not have teeth to assist in stabilizing the fracture. Phone consultation with an oromaxillofacial or plastic surgeon is essential to formulate an appropriate treatment plan.
PRIORITY ACTIONS

Suspicious mechanism of injury? Is the patient being physically abused? Unwitnessed head, neck, and facial injuries, particularly in women, should raise concern for interpersonal violence.

- Obtain a history with only the patient in the room, and ask directed questions concerning the mechanism of injury and patient circumstances.
- Contact appropriate resources if the patient confirms a history of physical abuse.

Typical concomitant injuries in a patient with facial trauma include contusions, intracranial pathology, and abdominal and cervical spine injuries.

- In patients with severe facial injuries, consider elevating the head of the bed to reduce facial soft tissue swelling and possible airway compromise.
- Reassess the patient for hemorrhage from a facial fracture on arrival and at 30-minute intervals up to 6 hours.

Is the patient experiencing sudden loss of vision or eye pain? Increased retrobulbar pressure from a hematoma or emphysema can lead to acute and permanent loss of vision.

- Lateral canthotomy can be a vision-saving intervention.
- Loss of the perception of light or the ability to identify colors without associated eye pain is indicative of optic neuropathy.
- Emergency consultation with an ophthalmologist and computed tomography of the orbits and globes are required when considering optic nerve impingement.

Pain with eye movement? Does the patient have muscle entrapment?

- Perform computed tomography of the maxilla and orbit when considering a blowout fracture of the orbit.

Loss of sensation in the nerve distribution?

- Superior orbital nerve: consider a superior orbital rim or frontal bone fracture.
- Inferior orbital nerve: consider a zygoma, inferior orbital rim, or maxillary fracture.
- Mandibular nerve: consider a mandibular fracture.

Does the patient have malocclusion? Consider a mandibular or maxillary fracture.

- The tongue blade test is useful as a clinical screening examination for mandible fractures.

Lacerations through the vermillion border require extra attention to detail with surgical closure. Slight misalignment at the time of wound closure may result in substantial cosmetic implications.

Competency of the parotid duct must be considered with all deep cheek lacerations.

Do not attempt to realign a fractured nose in the emergency department.

Does the patient have a septal hematoma?

- A septal hematoma requires immediate evacuation, application of a wound dressing, prophylactic antibiotics, and close follow-up for wound care.

Does the patient have an otohematoma?

- Otohematomas should be drained and an adherent pressure dressing applied to prevent reaccumulation.

Is the patient’s tetanus immunization up to date?

- Prophylactic antibiotics should be considered in patients with grossly contaminated wounds, open fractures, and joint wounds; in immunocompromised patients; with delayed wound closure; with high-velocity gunshot wounds; and in patients at high risk for endocarditis.

DOCUlATION

A detailed cranial nerve examination should be documented with special attention paid to the following:

- Ocular movements
- Sensory examination of the face
- Visual acuity
- Cervical spine “cleared” by clinical or radiographic criteria
- Absence of septal hematoma with a history of nasal trauma

Penetrating Neck Trauma

Niels K. Rathlev and Ron Medzon

**PATHOPHYSIOLOGY**

Unstable cervical spine fractures and spinal cord injuries are extremely unlikely in the presence of low-risk National Emergency X-radiography Utilization Study I (NEXUS I) criteria—that is, the patient:

1. Is alert and awake
2. Is not intoxicated
3. Has no signs or symptoms of neurologic injury
4. Has no spinous process tenderness

**ANATOMY**

The neck consists of three anatomic zones (see Fig. 77.1):

- **Zone I**—base of the neck to the cricoid cartilage (Fig. 77.2)
- **Zone II**—cricoid cartilage to the angle of the mandible
- **Zone III**—above the angle of the mandible (Fig. 77.3)

The major muscles of the neck are the platysma muscles, which extend from the lower jaw to the clavicle (Fig. 77.4). Other critical structures are shown in Figures 77.5 through 77.7.

**PRESENTING SIGNS AND SYMPTOMS**

**AIRWAY INJURY**

Symptoms of airway injury include dyspnea, hemoptysis, subcutaneous air, stridor, hoarseness, and dysphonia (Fig. 77.8).

**VAScular INJURY**

“Hard signs” that indicate severe vascular injury include the following:

- Bruit or thrill suggestive of a traumatic arteriovenous fistula
- Expanding or pulsatile hematoma
- Pulsatile or severe hemorrhage
- Pulse deficit—pulses may be normal in patients with nonocclusive injuries that require surgical repair, such as intimal flaps or pseudoaneurysms

**EPIDEMIOLOGY**

The incidence of injuries to the critical airway and the vascular, gastrointestinal, skeletal, and neurologic organs depends on the location and mechanism of injury. In the case of interpersonal violence, the distance between the assailant and victim and the type of weapon must be established. In total, 44% of injuries to critical organs involve vascular structures. This is a major source of morbidity and mortality (Table 77.1).

**PERSPECTIVE**

In the Vietnam War, the mortality from penetrating neck injuries was 4% to 7%. The current mortality rate in civilians is approximately 2% to 6%. Patients with zone I injuries (Fig. 77.1) at the base of the neck are at highest risk. Currently, spinal cord injuries and thrombosis of the common and internal carotid arteries account for 50% of all deaths from penetrating neck injury.
“Soft signs,” which are less predictive of severe vascular injury, include the following:

- Hypotension and shock
- Stable, nonpulsatile hematoma
- Central nervous system ischemia—a neurologic deficit that develops over the course of 1 to 2 hours after injury is consistent with ischemic neurologic injury; an immediate deficit is more likely to be due to a primary neurologic injury

- Proximity to a major vascular structure is not considered a high-risk feature in the absence of the preceding criteria (Fig. 77.9)

**DIGESTIVE TRACT**

The pharynx must be examined by visual inspection. Under normal conditions, the esophagus is mobile and collapsed. Symptoms and signs of esophageal injury include
subcutaneous air, crepitus, dysphagia, odynophagia, drooling, and hematemesis.

**DIAGNOSTIC TESTING**

**VASCULAR INJURY**

**Conventional Angiography**

The “gold standard” of diagnostic modalities is four-vessel angiography with venous-phase imaging (sensitivity > 99%) (Fig. 77.10). Very rarely do injuries missed by angiography require repair. A normal study is highly predictive of survival from vessel injury.  

**Duplex Ultrasonography**

Duplex ultrasonography is noninvasive, convenient, and relatively inexpensive, but its sensitivity in detecting vascular injury is highly operator dependent. However, its sensitivity in comparison with conventional angiography is 90% to 100% for injuries requiring intervention.  

Duplex ultrasonography can miss nonocclusive injuries with preserved flow, such as intimal flaps and pseudoaneurysms.
Multidetector Helical Computed Tomographic Angiography

This diagnostic modality has largely supplanted duplex ultrasonography in patients without obvious indications for immediate operative intervention (Fig. 77.11). The sensitivity of multidetector computed tomographic (MDCT) angiography is 90% to 100% with respect to conventional angiography and surgical exploration. Sensitivity is further improved with high-resolution computed tomography scanning, such as 64-row technology, and with increased technical experience using this modality. When compared with conventional angiography, MDCT
angiography is faster, less expensive, and noninvasive and does not involve interventional radiology.

PHARYNGEAL INJURY
Hypopharyngeal injuries may be difficult to visualize on radiographic contrast swallow studies, especially if patients are intubated. Videolaryngoscopy is an alternative diagnostic modality that is effective in detecting these injuries.6

ESOPHAGEAL INJURY
Esophageal injuries may be clinically silent initially. Radiographs do not exclude esophageal injury. Contrast-enhanced studies have a sensitivity of 50% to 90%. Esophagoscopy has a sensitivity of 43% to 100% (Table 77.2).

Rigid endoscopy has higher diagnostic yield than flexible endoscopy does; however, it is associated with a higher incidence of complications, including iatrogenic rupture. A combined approach that includes both contrast-enhanced studies and esophagoscopy has a sensitivity of 100%.7,8

complexity of the procedure in these patients. Partial airway injuries may lead to complete airway obstruction during endotracheal intubation. Hemorrhage should be controlled with direct pressure only. Spine immobilization is secondary to airway maintenance and control of bleeding in patients who are neurologically intact and awake.

AIRWAY INTERVENTIONS
Direct visualization of the airway is optimal, and orotracheal intubation is the initial method of choice because the procedure is frequently performed and rarely associated with complications. Ideally, intubation is accomplished with topical anesthesia while the patient is awake. If not possible, rapid-sequence induction should be performed. Fiberoptic intubation is reserved for elective airway management unless an experienced operator and the necessary equipment are immediately available. Visualization may be impaired because of extensive hemorrhage and secretions.
Cricothyrotomy or tracheostomy is necessary if orotracheal or fiberoptic intubation is unsuccessful. A surgical airway should not be delayed because an expanding hematoma can quickly distort the anatomy and result in complications. Intubation through an accessible neck wound has a very high success rate (Fig. 77.14). In this instance, care must be taken to control the proximal end of the trachea so that it does not retract into the thorax.
Nasotracheal intubation is not a preferred airway technique. Its success rate varies from 0% to 75%. It is potentially
associated with complications because of the “blind” nature of the procedure. A more direct, visualized approach is suggested (Fig. 77.15).

When diagnosed, injuries to the larynx or trachea are treated by primary surgical repair in the operating room. Immediate surgical exploration should also be performed in patients with progressive subcutaneous or mediastinal emphysema, pneumothorax, severe dyspnea, or associated esophageal trauma. This is followed by a mid or low tracheostomy, depending on the site of the injury.

**WOUND CARE AND EVALUATION**
The emergency physician (EP) may gently spread the wound edges without probing. The patient should be placed in the Trendelenburg position if there is any concern about internal jugular vein injury and possible air embolism. Wounds should be closed only if the depth is clearly visualized; caution is urged because assessment of depth is difficult. The EP must suspect deep penetration and ensure complete diagnostic evaluation.

**Vascular Injury**
Direct pressure should be used; blindly clamping structures with poor visualization should be avoided. Pharyngeal packing for severe oral bleeding may be necessary. Subclavian vein injury should be suspected in patients with zone I injuries. Intravenous access should be established on the side opposite the injury to avoid potential extravasation of fluids.

Emergency department thoracotomy is indicated for patients with zone I injuries and refractory shock. Subclavian artery injury should be suspected in these cases. Treatment is determined by angiographic grading of the vascular injuries. Primary repair is preferred over graft placement when possible.

Surgical repair of carotid and vertebral artery injuries is preferred over ligation except in the following cases:

- Coma without antegrade flow because of the high risk of converting an ischemic to a hemorrhagic brain injury
- Uncontrollable hemorrhage
- Inability to place a temporary shunt

**Esophageal Injury**
Delay in diagnosis and repair of esophageal injuries is associated with increased morbidity and mortality because of the potential for mediastinitis. When surgery is performed less than 24 hours after the injury, the survival rate is greater than 90%; when surgery is performed more than 24 hours after the injury, it is just 65%.

**Cervical Spine Injury**
Rigorous spinal precautions should not be maintained at the expense of managing life-threatening airway or vascular injuries in patients who are awake and neurologically intact without focal deficits. Unstable spine fractures are almost
invariably associated with focal neurologic deficits or altered mental status. Early fracture stabilization and fixation are mandatory. Corticosteroids have no role in spinal cord injury caused by penetrating trauma.

**ADMISSION AND DISCHARGE**

Admission criteria include (1) any signs or symptoms of organ damage and (2) penetration of the platysma, which is only 2 to 3 mm in depth.

**PATHOPHYSIOLOGY**

The most common mechanism of blunt thoracic trauma is an MVC, followed by falls, assaults, and crush injuries. Compressive forces directly injure the thoracic cage and underlying viscera and result in rib fractures and pulmonary contusion. Deceleration produces traction on fixed structures such as the isthmus of the aorta and the carina and results in traumatic aortic and tracheobronchial injuries. Blunt thoracic trauma causes penetrating thoracic trauma when rib or clavicle fractures impale thoracic or abdominal viscera.

Gunshot wounds and stab wounds are the most common mechanisms of penetrating thoracic trauma. Low-velocity stab wounds disrupt only the structures penetrated. Medium-velocity handguns and high-velocity military assault rifles produce temporary and permanent cavities of tissue damage. Missile injuries to the thorax often involve multiple anatomic regions, including the neck, diaphragm, abdomen, and retroperitoneum.

**EPIDEMIOLOGY**

Head and thoracic injuries from moving vehicle collisions (MVCs) and firearms account for the majority of the more than 160,000 injury-related deaths in the United States each year. Most fatalities occur immediately as a result of massive cardiac or vascular injury. Rib fractures are the most common thoracic cage injury following blunt thoracic trauma. Isolated first and second rib, sternum, and scapula fractures are no longer considered markers of traumatic aortic injury. However, rib fractures must still be considered markers of significant injury. Most patients seen in trauma centers with rib fractures will have hemothorax, pneumothorax, or a pulmonary contusion. Three or more rib fractures at any anatomic site dramatically increases the risk for spleen and liver injury. Likewise, scapula fractures are uncommon yet signify a high-energy mechanism of injury, almost always with important associated injuries.

Seat belts have increased the incidence of sternum fractures while reducing the number of lives lost in MVCs. Isolated nondisplaced sternum fractures are no longer considered markers of blunt cardiac injury. More complicated fracture patterns predict associated injuries. Fractures of the manubrium, manubrium-sternum synchondrosis, and proximal part of the sternum and severely displaced sternum fractures are associated with an increased incidence of spinal fractures. Displaced fractures of the body of the sternum are associated with a higher incidence of intrapulmonary and cardiac injuries.

**Thoracic Trauma**

**KEY POINTS**

- Emergency life-threatening conditions that need to be detected during the primary survey include airway obstruction, tension pneumothorax, open pneumothorax, massive hemothorax, flail chest, and pericardial tamponade (Table 78.1).
- Urgent life-threatening conditions to detect during the secondary survey include simple pneumothorax, hemothorax, pulmonary contusion, tracheobronchial injury, blunt cardiac injury, traumatic aortic injury, diaphragmatic injury, and esophageal injury.
- Common thoracic cage injuries are not always associated with serious injury, but some individuals, especially pediatric and elderly patients, may require admission for associated injuries and respiratory therapy.

**THORACIC CAGE INJURIES: RIB, STERNUM, AND SCAPULA FRACATURES**

MVCs are the most common cause of rib and sternum fractures. Other mechanisms include pedestrian injury by a moving vehicle, falls, contact sports, and altercations. Fractures occur at the site of direct blows or at their posterior weak point as a result of compressive forces. Ribs 4 to 9 are the most commonly fractured.

All thoracic cage injuries result in significant pain, splinting, atelectasis, and increased risk for pneumonia. Multiple rib fractures interfere directly with the mechanics of ventilation. Fracture fragments may penetrate the pleura and lungs and result in pneumothorax and hemothorax. Traditionally, fractures of the 6th to 12th rib on the right suggest liver injury and on the left suggest splenic injury. However, any fracture, especially multiple fractures, increases the risk for liver and splenic injuries.
Because children have more elastic chest walls, more energy is transmitted to the underlying lung, and greater force is required for fractures. Excluding other major trauma, 71% of rib fractures in children younger than 2 years result from abuse.5

**PRESENTING SIGNS AND SYMPTOMS**

Classically, rib fractures are accompanied by localized tenderness and pleuritic chest pain, as well as splinting, crepitus, and ecchymosis. Patients with a classic sternum fracture have localized pain and tenderness along with ventral compression, ecchymosis, and deformity. Pain at the site of thoracic cage injuries increases with cough and deep inspiration. Patients with scapular fractures typically have rib and extremity fractures that often mask the diagnosis of scapula fracture.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The initial portable anteroposterior (AP) chest radiograph should be inspected to confirm the diagnosis of rib fracture and underlying pleura or lung injury. Upright posteroanterior (PA) and lateral radiographs should be obtained if a high clinical index of suspicion remains for fracture or underlying injury. The presence of an occult “clinical rib fracture” with tenderness over the rib should be assumed even in the absence of radiographic findings. Rib radiographs seldom add to the clinical evaluation and are not routinely indicated.

Sternum fractures are best detected on the lateral chest radiograph. Associated rib fractures and mediastinal abnormalities may be evident on the PA view. In experienced hands, bedside ultrasound may be more sensitive than radiographs for detection of both rib and sternum fractures, as well as associated hemothorax or pneumothorax.6,7 The electrocardiogram (ECG) should be examined for evidence of cardiac injury. Scapula fractures are often missed on the initial chest radiograph unless the scapular outline is specifically inspected. Shoulder radiographs can confirm suspected fractures (Fig. 78.1).

Helical computed tomographic (CT) angiography should be performed on hemodynamically stable patients when clinically significant underlying injury is suspected. An abdominal CT scan can rule out intraabdominal injury in patients with tenderness or fracture of the sixth rib or below, three or more rib fractures, hypotension noted in the field or emergency department (ED), abdominal or flank tenderness, pelvic or femoral fractures, or gross hematuria.8

**TREATMENT**

Adequate pain control should be provided to prevent atelectasis in patients with simple acute rib fractures. Patients should be instructed to perform incentive spirometry or take 10 deep breaths every hour. Binders and belts are not recommended because such devices promote hypoventilation, which results in atelectasis and pneumonia. Shoulder slings and pendular exercise should be prescribed for most scapular fractures. Displaced fractures, especially those involving the scapular spine and neck, often require consultation with an orthopedic surgeon for repair.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Otherwise healthy patients with isolated rib fractures or sternum or scapula fractures may be discharged home. Elderly

CPAP, Continuous positive airway pressure; Dx, diagnostic testing; ECG, electrocardiogram; JVD, jugular venous distention.
Flail chest occurs when three or more ribs are fractured in two or more places and a discontinuous segment of the thoracic wall is produced and moves paradoxically with respiration. Flail chest is diagnosed in approximately 5% of thoracic trauma patients seen in level I trauma centers, typically in the setting of multisystem trauma. Mechanisms include MVCs, crush injuries, assault, falls, and even minimal trauma in elderly patients. Respiratory insufficiency results primarily from the underlying pulmonary contusion. Pneumothorax occurs in 50% of cases and pulmonary contusion in 75%.9

PRESENTING SIGNS AND SYMPTOMS

Patients may have the classic signs and symptoms of respiratory distress, tenderness, crepitus, deformity, and paradoxical motion of the affected thoracic wall. Affected segments will move inward during inspiration and outward during expiration. More commonly, splinting secondary to severe pain or mechanical ventilation masks the diagnosis. Forced expiration and coughing accent the paradox.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

A chest radiograph can confirm the diagnosis and detect complications such as pneumothorax and hemothorax. A chest CT scan can further evaluate the underlying pulmonary contusion and assess for other underlying injuries such as traumatic aortic injury.

TREATMENT

Immediate chest tube placement is required for assessment and management of other injuries, including pneumothorax and hemothorax. Continuous positive airway pressure is the first-line treatment in awake and cooperative patients with worsening oxygenation or ventilation.10 Criteria for intubation include airway obstruction, respiratory distress, shock, closed head injury, and need for surgery. Endotracheal intubation should be performed only when necessary to avoid the increased mortality associated with nosocomial pneumonia.

Fluid replacement should be managed carefully to avoid overhydration and worsening of lung injury. Analgesia is titrated so that patients are more willing to make sufficient inspiratory effort, but excessive sedation should be avoided. Intercostal nerve blocks, epidural anesthesia, or even surgical fixation of the flail segment may be beneficial.11 Stabilization of the flail segment in the ED or prehospital setting has not been shown to be helpful, and aggressive stabilizing efforts impede overall thoracic mechanics.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Consultation and admission for trauma or cardiothoracic surgery is advised when flail chest is suspected. Overall mortality from flail chest, though dependent on other injuries, ranges up to 35%. All patients with flail chest should be admitted to the intensive care unit, preferably at a level I trauma center for close observation of respiratory mechanics and worsening of pulmonary contusion.

PNEUMOTHORAX AND HEMOTHORAX

A simple pneumothorax occurs when air accumulates in the pleural space without shifting the mediastinum or communicating with the atmosphere. Mechanisms include laceration of the pleura or lung by a fractured rib, alveolar rupture from compression of the chest against a closed glottis, or a penetrating wound in the thorax.

Tension pneumothorax occurs when injury to the chest wall acts as a one-way valve. Outside air enters the pleural space...
during inspiration but cannot exit during expiration. Accumulating air increases intrapleural pressure, which eventually shifts the mediastinum, compresses the vena cava, reduces venous return, and ultimately decreases cardiac output. Open or communicating pneumothorax occurs when a significant thoracic wall defect causes the lung to collapse on inspiration and expand on expiration, with air being “sucked” into and out of the chest and thus preventing effective ventilation. Mechanisms include high-velocity assault rifle injuries and shotgun wounds.

Hemothorax occurs when blood accumulates in the pleural space, typically from minor lacerations in the lung parenchyma. Massive hemothorax is defined as greater than 1.5 L of blood in the initial chest tube drainage and is an indication for immediate surgery. Hemopneumothorax occurs when both air and blood fill the pleural space and commonly results from rib fractures or penetrating trauma.

**PRESENTING SIGNS AND SYMPTOMS**

Patients with a simple pneumothorax classically have chest pain, diminished breath sounds, crepitus, hyperresonance, and mild to moderate respiratory distress. Patients with tension pneumothorax are classically seen in extremis and exhibit jugular venous distention, tracheal deviation, unilaterally absent breath sounds, or tachycardia followed by hypotension immediately before death (or any combination thereof). Patients with open pneumothorax have chest wall wounds that produce sonorous sounds and are in severe respiratory distress. Typical symptoms of hemothorax are respiratory distress, chest pain, and diminished breath sounds with dullness to percussion.

Atypical manifestations are more common than classic ones. Respiratory distress may occur as a result of multiple other causes. Patients can have severe pain from distracting injuries. Breath sounds may be difficult to hear in a noisy environment. Physical examination in patients with penetrating thoracic trauma is unreliable for the detection of pneumothorax or hemothorax. Patients with simple pneumothorax may be minimally symptomatic or may be cyanotic and in severe respiratory distress. Tension pneumothorax most commonly occurs in intubated patients as a result of positive pressure ventilation, sometimes after overzealous bagging.

Clinical reassessment of ventilated patients with decreasing oxygen saturation and hypotension may allow faster detection and treatment, even before chest radiographic diagnosis. Open pneumothorax may be missed if the patient is not completely exposed and rolled during the primary survey.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis for tension pneumothorax includes cardiac tamponade, massive hemothorax, and right mainstem intubation with left lung collapse. All will produce respiratory distress, hypotension, and tachycardia. Cardiac tamponade results in diminished heart sounds with normal breath sounds and a midline trachea. Massive hemothorax produces decreased or absent unilateral breath sounds and dullness to percussion. Chest tube insertion confirms the diagnosis. Right mainstem intubation results in jugular venous distention, tracheal deviation to the left, normal resonance, and diminished breath sounds on the left versus the right. In an intubated patient, the endotracheal tube should be checked and pulled back. In the field or resuscitation bay, bilateral needle thoracostomy should be performed when the patient is in distress, even if the diagnosis is uncertain. A rush of air confirms the diagnosis of tension pneumothorax. Chest tubes must be placed after needle decompression.

A chest radiograph can confirm the diagnosis of simple pneumothorax and hemothorax. A distance of 1 cm or one fingerbreadth between the chest wall and visceral pleural line correlates with a small, 10% to 15% pneumothorax. Anything larger requires immediate chest tube insertion. On a supine portable AP chest radiograph, a deep sulcus sign suggests pneumothorax. The affected costophrenic angle appears clearer and deep with depression of the hemidiaphragm as a result of localized air collection in a supine patient. In patients with a high index of clinical suspicion based on symptoms or penetrating injuries, some authorities advocate expiratory upright PA and lateral chest radiographs to make the lung volume smaller and the pneumothorax volume relatively larger and easier to visualize. Clinically significant pneumothorax should be evident on standard chest radiographs. The chest CT scan is more sensitive in visualizing pneumothorax; it often detects small occult pneumothoraces, which require close monitoring.

In an upright patient, a hemothorax appears as a fluid layer in the affected hemithorax. Early collections are noted to blunt the costophrenic angles on the AP and lateral radiographic views. Hemothorax often appears as only a diffuse hazy infiltrate in a supine trauma patient. Hemopneumothorax has a fluid layer with a flat superior border, in contrast to the round meniscus of an isolated hemothorax (Figs. 78.2 and 78.3). Decubitus views better demonstrate a small hemothorax.
An extended focused assessment with sonography for trauma (FAST) scan can diagnose pneumothorax and hemothorax with higher sensitivity than portable chest radiography can in experienced hands. An extended FAST scan is especially helpful when chest radiography is not immediately available and in mass casualty situations.14

**TREATMENT**

Tension pneumothorax and open pneumothorax are both clinical diagnoses that require immediate treatment with needle thoracostomy followed by tube thoracostomy, even when based on clinical evaluation, before radiographic confirmation. All suspicious open chest wounds should be covered with petrolatum gauze secured on three sides to prevent the entry of air during inspiration and allow the exit of air during expiration. Postprocedure radiographs should be obtained to confirm placement, drainage of air and blood, and reexpansion of lung. Prophylactic antibiotics with chest tube insertion do not reduce the risk for empyema or pneumonia.15

Operating room thoracotomy is indicated for patients with massive hemothorax (initial drainage of 1.5 to 2 L of blood), persistent bleeding of more than 200 mL/hr for 4 hours, and persistent hypotension or instability despite blood replacement. Autotransfusion should be performed in patients with massive hemothorax or persistent significant bleeding. It is prudent to prepare for autotransfusion early because most blood loss occurs at the time of initial chest tube insertion.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Traumatic pneumothorax and hemothorax generally require tube thoracostomy. The exception is a small stable pneumothorax in an otherwise healthy and symptom-free patient, which may be managed with observation.

Occult traumatic pneumothorax detected on a CT scan requires only close observation for respiratory distress, progression, and the development of complications. Tube thoracostomy must be immediately available but is not required even with positive pressure ventilation.16 Any prolonged surgery, diagnostic testing, or transport preventing immediate tube thoracostomy requires prophylactic placement.

In patients with penetrating injuries and a negative initial chest radiograph, upright PA and lateral chest radiographs should be repeated in 3 to 4 hours.17 Patients with normal findings on repeated radiographs and no significant associated injuries are discharged with wound care and follow-up instructions. Patients with asymptomatic blunt chest trauma and normal findings on the initial chest radiographs do not require repeated films before discharge. All patients with chest tubes are admitted to the trauma, cardiothoracic, or general surgery service in the care of personnel experienced in managing chest tube equipment.

**PULMONARY CONTUSION**

Pulmonary contusion is the most common parenchymal lung injury in victims of blunt chest trauma. Though typically described in the setting of flail chest, pulmonary contusion can occur with less significant chest wall fractures and occasionally even in the absence of overlying injury.

Pulmonary contusion occurs with blunt, blast, or high-energy penetrating injuries. MVCs and falls are the most commonly reported mechanisms. Injury to the lung-parenchyma causes hemorrhage and edema of the alveoli and interstitium, which results in ventilation-perfusion mismatching and ultimately hypoxia and hypercapnia. Hemorrhage worsens over the first 24 to 48 hours and then typically resolves over the next 7 days. Acute respiratory distress syndrome and pneumonia are the most frequent complications, both with significant morbidity and mortality.

**PRESENTING SIGNS AND SYMPTOMS**

Patients with pulmonary contusion typically have significant chest wall injury accompanied by dyspnea and tachypnea and progressing to hemoptysis, cyanosis, and hypotension. Inspection often reveals an obvious flail chest or ecchymosis overlying rib fractures. Auscultation reveals rhonchi, wheezes, rales, or minimal breath sounds. Blast injuries may result in significant pulmonary contusion with minimal chest wall injury. Delayed manifestations of pulmonary contusion can occur in initially well-appearing patients. Because the hemorrhage and edema will worsen, patients with even mild initial symptoms must be observed closely with continuous monitoring. The clinical findings usually progress over the initial hours through the first 2 days.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis in a trauma patient with respiratory distress and infiltrates on initial chest radiographs includes pulmonary contusion, congestive heart failure, aspiration pneumonia, and acute respiratory distress syndrome. Symptomatic congestive heart failure may predispose patients to blunt trauma, result from blunt myocardial injury, or develop during fluid resuscitation. Aspiration pneumonia leads to
higher in patients with larger areas of contusion, flail chest, acute respiratory distress syndrome, and pneumonia.

**TRACHEOBRONCHIAL INJURY**

Tracheobronchial injuries are infrequent but present unique challenges to the emergency physician (EP). Emergency airway management is often both required and complicated by these devastating injuries.

Penetrating tracheobronchial injuries are more common than blunt injuries. Penetrating injuries to the relatively exposed cervical trachea occur more frequently than injuries to the protected thoracic trachea. Gunshot wounds involving the thoracic trachea occur more often than stab wounds. Blunt injuries to the cervical trachea occur with rapid deceleration and result in shear stress at the junction of the larynx and trachea; examples of these types of injury include hyperventilation injury, direct dashboard strikes, and "clothesline" injuries in snowmobile and motorcycle accidents.

Blunt injuries to the thoracic trachea are typically caused by high-energy MVCs, crush injuries, and falls. Rapid deceleration produces a shearing force with injury typically within 2 cm of the fixed carina. Injuries to the esophagus and spine are the most common associated injuries. Head, vascular, nerve, and intrathoracic injuries also occur frequently with both blunt and penetrating tracheobronchial injuries (Box 78.1).

**PRESENTING SIGNS AND SYMPTOMS**

Patients with tracheobronchial injuries typically have dramatic but nonspecific symptoms, including hoarseness, dysphagia, hemoptysis, and dyspnea. Careful inspection for penetrating wounds should be made, and the trajectory and proximity of the injury to the trachea should be estimated. Findings on physical examination include escape of air from wounds, subcutaneous emphysema in the neck and supraclavicular region, hypoxia, stridor, pneumothorax, and pneumomediastinum. Patients with blunt trauma often have few signs of external injury. Persistent air leaks despite a functioning chest tube suggest tracheobronchial injury. Rarely, patients with tracheobronchial injuries without communication with the pleural space maintain respiration with minimal symptoms until granulation tissue obstructs the airway and results in delayed lobar atelectasis.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Chest radiographs may have subtle evidence of tracheobronchial injuries such as high rib fractures, the fallen lung sign, pneumomediastinum, deep cervical emphysema, peribronchial air, abnormal location of the endotracheal tube, and a spherical shape of the normally oval endotracheal tube balloon. The fallen lung sign occurs when the apical segments of the lung have collapsed and fallen to the level of the hilum. Flexible fiberoptic bronchoscopy usually confirms the injury. Helical CT angiography is particularly effective in diagnosing blunt laryngeal injury and often provides additional informa-
CHAPTER 78  THORACIC TRAUMA

BOX 78.1 Approach to Thoracic Trauma

Blunt Trauma
High-energy mechanisms: Falls greater than 3 m or motor vehicle collisions at more than 30 mph
All injuries: CXR and pulse oximetry. If pneumothorax or hemothorax, insert a chest tube
Traumatic aortic injury: A mechanism with chest wall tenderness or abnormal CXR evidence requires helical CT angiography; if negative, evaluate for traumatic aortic injury; if findings indeterminate, obtain an aortogram; if positive, transfer the patient to the operating room
Blunt cardiac injury: With abnormal ECG, hypotension, or dysrhythmia, cardiac monitoring and hospitalization for 24 hours with repeated ECGs every 8 hours; with hypotension or symptomatic dysrhythmia, formal echocardiography

Penetrating Injuries
All injuries: Continuous pulse oximetry and PA and lateral CXR at 0 and 6 hours
Anterior cardiac box: FAST examination to evaluate for pericardial fluid
Posterior box and transmediastinal gunshot wounds: Angiography for great-vessel injury; with signs and symptoms of injury, esophagography or esophagoscopy and bronchoscopy
Posterior box stab wounds: If abnormal mediastinum on CXR, angiography for great-vessel injury; with signs and symptoms of injury, esophagography or esophagoscopy and bronchoscopy
Thoracoabdominal: DPL with a red blood cell count of 10,000 cells/µL, laparoscopy/thoracoscopy or laparotomy to evaluate for diaphragmatic injury

CT, Computed tomography; CXR, chest radiograph; DPL, diagnostic peritoneal lavage; ECG, electrocardiogram; FAST, focused assessment with sonography for trauma; PA, posteroanterior.
*Protocols and approach may vary depending on institutional experience and availability.

During orotracheal intubation, a smaller-size endotracheal tube should be inserted and placed past the injury if possible. To prevent worsening of the injury, force should be avoided during placement of the endotracheal tube. When orotracheal intubation is not possible, the endotracheal tube should be placed through the anterior neck wound into the trachea. The EP must be careful to avoid pushing a transected trachea deeper into the thorax. In patients with complete transection and retraction of the trachea, major intervention is required. A right-sided thoracotomy should be performed (to avoid the aortic arch on the left), and the EP should attempt to visualize the injured trachea, support it, and establish an airway. Extension to a left-sided thoracotomy may be needed for complex distal injuries. Tube thoracostomy is required, often with multiple tubes to drain the resulting pneumothorax and reexpand the affected lung.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Stable patients with tracheobronchial injuries and a maintained airway are best transported to the operating room immediately for fiberoptic bronchoscopy, intubation, and possible thoracotomy. Definitive surgical repair is necessary to prevent acute and late complications. Acute complications include persistent air leak, pneumothorax, empyema, and mediastinitis. Delayed complications include granulation of partial injuries with resultant atelectasis and significant loss of pulmonary function. Penetrating and blunt injuries are typically managed early by exploration and repair.

BLUNT CARDIAC INJURY

The pathologic spectrum of blunt cardiac injury begins with cardiac concussion; includes myocardial contusion, coronary artery injury, and valve and septal injury; and ends with myocardial rupture. Myocardial contusion remains the most common clinical challenge to the EP. A definitive diagnosis can be made only at autopsy, and complications are rare but life-threatening.

Blunt cardiac injury typically results from MVCs but may occur after falls, crush injuries, blast injuries, direct blows, and chest compression. Low-speed deceleration injuries occasionally result in significant injury. Proposed mechanisms include compression of the heart between the sternum and vertebral bodies and sudden striking of the heart against the sternum in deceleration injuries.

Cardiac concussion, or commotio cordis, occurs when a blow to the chest briefly “stuns” the heart; it results in dysrhythmia, hypotension, syncope, and often sudden death but without permanent cellular damage. Commotio cordis may result from an anterior chest wall impact at a moment when the myocardium is refractory to depolarization and can result in fatal arrhythmia, also known as the R-on-T phenomenon.

Myocardial contusion occurs when injury to the anterior wall, formed by the right ventricle, results in well-defined areas of red blood cell extravasation and eventually in subendocardial and transmural necrosis. Infrequent delayed complications include mural thrombus, pericardial effusions,
constrictive pericarditis, and ventricular aneurysms. Direct injury to already atherosclerotic coronary arteries or severely contused myocardium can result in myocardial infarction. The rare blunt cardiac rupture is typically immediately fatal except when limited to the low-pressure right side of the heart or to small, self-sealing ventricular injuries.

**PRESENTING SIGNS AND SYMPTOMS**

Blunt cardiac injury typically occurs in patients with multiple blunt trauma injuries. Patients with commotio cordis generally experience immediate dysrhythmia and loss of consciousness. Though usually fatal, the survival rate is increasing as a result of increased public awareness, immediate cardiopulmonary resuscitation, and increased availability of automatic external defibrillators.\(^2^1\)

Patients with myocardial contusion typically complain of angina-type chest pain unrelieved by nitroglycerin, pleuritic pain, or pain from associated injuries. Evidence of external trauma is usually but not always present. Information about the scene of the injury often provides the only evidence of blunt cardiac injury.

Initial and vital sign trends should be carefully noted, including mental status, color, jugular venous distention, and the presence of chest wall ecchymosis or tenderness, gallop rhythms, and friction rubs. Persistent unexplained tachycardia, hypotension, or dysrhythmia suggests blunt cardiac injury. Patients with valve dysfunction typically have a loud murmur, acute heart failure, and jugular venous distention. The rare patient with cardiac rupture who survives to arrive at the ED generally exhibits signs of cardiac tamponade or overt cardiogenic shock.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

An ECG should be recorded in all patients with suspected blunt cardiac injury. Traditionally, stable patients with normal results on the initial ECG were considered to be at low risk for complications and safe for discharge. However, more recent literature suggests that patients may still be at risk for complications of blunt cardiac injury, including lethal dysrhythmias up to 12 hours after trauma and non–life-threatening dysrhythmias up to 72 hours later.\(^2^2\) New findings on the ECG suggestive of myocardial contusion include unexplained tachycardia, ST- and T-wave changes, conduction abnormalities, and dysrhythmias.

Evaluation of cardiac markers is not routinely indicated in patients with blunt cardiac injury. The exception is serial troponin I measurement in patients with an ischemic pattern on the initial ECG and in patients in whom cardiac ischemia may have precipitated the trauma. However, a recent metaanalysis supports the use of troponin I as a sensitive test for myocardial contusion when determined at admission and 4 to 6 hours later.\(^2^3\)

Emergency bedside echocardiography is recommended for unstable patients with suspected blunt cardiac injury or with evidence of myocardial infarction on the ECG. Pericardial effusions are easily identified on the initial subxiphoid view of the FAST scan. Formal echocardiography with parasternal and apical views will better identify small effusions, valve dysfunction, and wall motion abnormalities. Transesophageal echocardiography is more sensitive than transthoracic echocardiography and provides additional imaging of the aorta in unstable patients. Routine echocardiography does not predict complications in stable patients with suspected blunt cardiac injury.

**TREATMENT**

Unstable patients with blunt cardiac injury require definitive airway control to ensure optimal oxygenation and ventilation. A large-bore internal jugular catheter should be inserted for fluid resuscitation, monitoring of central venous pressure, and placement of a Swan-Ganz catheter. Cardiogenic shock secondary to myocardial contusion or cardiac rupture typically requires careful fluid replacement and inotropic support. Refractory cases may require temporary stabilization with an aortic balloon pump after an aortic injury has been ruled out. Cardiac catheterization is necessary in patients with myocardial infarction because antithrombotic therapy is contraindicated after trauma.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Stable patients with a normal initial ECG and without significant associated injuries can be safely discharged from the ED. Stable patients with changes on the ECG suggestive of myocardial contusion require observation with continuous monitoring for 24 hours and electrocardiography repeated every 8 hours for 24 hours. Brief dysrhythmias seldom require treatment, and prophylactic antidysrhythmic therapy is not indicated.

Unstable patients with ventricular dysrhythmias, atrial fibrillation, sinus bradycardia, and bundle branch block require intensive care unit admission. In patients with abnormal findings on the initial ECG, the complication rate is low, with complications predominantly occurring in older patients with multiple injuries. Wall motion abnormalities and rhythm disturbances typically resolve within hours. Most patients with myocardial contusion require only supportive care and aggressive management of complicating injuries. Morbidity and mortality are directly related to the presence of other injuries.

**PENETRATING CARDIAC INJURY, CARDIAC TAMPONADE, AND EMERGENCY DEPARTMENT THORACOTOMY**

Penetrating cardiac injuries most commonly result from gunshot wounds, followed by stab wounds. Any gunshot wound involving the torso can result in penetrating cardiac injury. Survival is better in patients with stab wounds, single-chamber involvement, and low-pressure right heart injuries.
Cardiac tamponade most commonly results from stab wounds to the chest or upper part of the abdomen, followed by gunshot wounds and infrequently by blunt chest trauma. Penetrating injuries to the heart result in either death at the scene or tamponade, which allows transport to the ED. Tamponade is more likely to occur with smaller injuries from stab wounds. The tough fibrous sac surrounding the heart prevents immediate exsanguination. As blood accumulates, cardiac filling and eventually output are impaired, which often results in rapid decompensation after arrival at the ED. Acutely accumulated pericardial blood may be difficult to visualize on cardiac ultrasonography. The right ventricle is the most commonly injured structure, followed by the left ventricle. Approximately three of four patients will die of the injury.

**PRESENTING SIGNS AND SYMPTOMS**

Patients with pericardial tamponade classically but uncommonly exhibit the Beck triad of hypotension, jugular venous distention, and muffled heart sounds. Most patients will have at least one of these signs, with all three appearing only briefly before cardiac arrest. More frequently, patients either appear relatively stable or are in extremis. Stable-appearing patients have small wounds in the pericardium that allow intermittent decompression of the accumulated blood. Patients with more rapid accumulation are panic-stricken, appear to be in severe respiratory distress, and often have needle thoracostomy performed for presumed tension pneumothorax. In these patients, agitation, tachycardia, and hypotension predominate before progressing to obtundation, bradycardia, and pulseless electrical activity.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

An ultrasonographic subxiphoid view (Fig. 78.5) may detect pericardial fluid in patients with suspected cardiac injury. Pericardial fluid with diastolic collapse of the right atrium and ventricle is diagnostic of pericardial tamponade. Any pericardial effusion in unstable trauma patients with equal bilateral breath sounds signals tamponade requiring immediate operative intervention. Although the sensitivity of FAST scans approaches 100% for hemopericardium, false-negative results may occur when blood drains rapidly into the thorax. The possibility should be considered in patients with small anterior stab wounds and persistent left hemotorax despite tube thoracostomy.24

An initial ECG should be obtained to evaluate for findings suggestive of pericardial tamponade and other cardiac injury. Electrical alternans, low voltage, and PR-segment depression are specific but not sensitive for the diagnosis of pericardial effusion. A chronic pericardial effusion is more likely to reveal such findings. Acute traumatic pericardial effusion resulting in tamponade does not change the size of the heart on the chest radiograph. However, a chest radiograph can be useful in identifying other injuries and the presence of retained foreign bodies. It is important to remember that normal findings on the ECG and chest radiograph do not rule out traumatic pericardial effusion or tamponade.

**TREATMENT**

A central venous line should be placed for volume infusion and monitoring of central venous pressure. The injured hemithorax is preferred for central line placement to avoid iatrogenic complications in the uninjured side. The exception is a patient with obvious injury to the clavicle and suspected injury to the subclavian vein.

Aggressive fluid resuscitation is mandatory for patients with suspected pericardial tamponade to maximize cardiac filling pressure and cardiac output. Elevated central venous pressure in persistently hypotensive and tachycardic trauma patients suggests impending tamponade. Pericardiocentesis with catheter placement should be performed in patients with deteriorating vital signs. Pericardiocentesis may serve as a diagnostic and temporizing measure but is never a replacement for thoracotomy and definitive repair of the injury. Ultrasonography or ECG-guided pericardiocentesis is preferred, if available. Nonclotting blood traditionally signifies pericardial blood, but aspiration may be unsuccessful because of needle placement, continuous brisk pericardial bleeding, or other reasons. However, removal of even a small amount of pericardial blood can restore vital signs and aid survival until surgical intervention is available.

Thoracotomy is reserved for patients with cardiac tamponade who are in cardiac arrest or impending arrest. The likelihood of functional survival after ED thoracotomy is greatest for victims of stab wounds with isolated cardiac injury who have signs of life on ED arrival. At the trauma center, thoracotomy is performed on victims of penetrating trauma who experienced cardiac arrest in the ED or within 10 minutes of arrival at the ED and on blunt trauma patients who experienced cardiac arrest in the ED. In the ED without surgical support, thoracotomy is best performed by a skilled EP only on patients with thoracic stab wounds or isolated gunshot
wounds who lost signs of life in the ED or within 10 minutes of arrival in the ED. In all other cases, ED thoracotomy should be performed only if a qualified surgeon is present or immediately available (Table 78.2).

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Immediate operative repair is indicated for all penetrating injuries of the heart to relieve tamponade and repair the initial injury. Identification and initial management of all associated injuries ensure optimal outcomes, but operative intervention must not be delayed. Diagnostic peritoneal lavage should be performed in the operating room to identify intraperitoneal bleeding and assess the need for laparotomy.

GREAT VESSEL INJURY

Great vessel injury is a significant cause of morbidity and mortality with both blunt and penetrating thoracic trauma. Traumatic aortic injury is the second most common cause of blunt traumatic death. Eighty percent of victims of traumatic aortic injury die immediately. The majority of survivors can be saved with prompt ED diagnosis, blood pressure control, and operative repair. Five percent of patients will be unstable on arrival and have a mortality rate of up to 98%. The remaining 15% will be hemodynamically stable, which often contributes to a delay in diagnosis and a mortality rate as high as 25%.29

The descending aorta is fixed within the thorax by the ligamentum arteriosum and the intercostal arteries. Sudden deceleration causes the aortic arch to swing forward and produces a shearing force with resultant injury just distal to the takeoff of the left subclavian artery. Traditionally, traumatic aortic injuries have been considered only in patients with “major mechanisms of injury,” including high-speed MVCs with frontal or side impact and motorcycle crashes. However, the injury has been reported with less impressive mechanisms such as pedestrian-versus-auto collisions, falls, and crush injuries. Use of restraint systems does not protect persons from traumatic aortic injuries.20,31 Penetrating injuries to the great vessels typically result from both gunshot penetration and stabbing.

PRESENTING SIGNS AND SYMPTOMS

Signs and symptoms of traumatic aortic injury are often not present or are masked by other injuries. Up to one half of all patients have no signs of chest wall injury. Common signs and symptoms include interscapular or retrosternal pain, decreased blood pressure in the left arm, upper extremity hypertension with absent femoral pulses, bruit, and a harsh systolic murmur heard over the precordium or interscapular area. Uncommon findings include extremity pain from distal ischemia, dysphagia from concomitant esophageal injury, and hoarseness as a result of compression of the laryngeal nerve.

Evidence of penetrating injury to the great vessels depends on the mechanism and location of the injury. High-energy proximal arterial injury typically results in immediate exanguination or hemorrhagic shock with massive hemothorax. Contained mediastinal hematoma can occasionally impair superior vena cava return and produce engorgement of the soft tissues of the neck, face, and airway. Distal injuries may result in diminished pulses, expanding hematomas, and limb ischemia. Careful palpation for pulse symmetry and measurement of blood pressure in both arms are advisable.

Stab wounds should be inspected carefully to help determine the general trajectory. Deep probing of wounds should be avoided to prevent iatrogenic worsening of the initial injury, dislodgment of clot and massive hemorrhage, and infection. Chest tube output should be closely monitored. The chest tube should be clamped when the patient is being transported to the operating room; when massive hemothorax and heavy, continuous bleeding are present, temporary tamponade within the pleural cavity may be required for this short time.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The initial chest radiograph should show evidence of traumatic aortic injury (Fig. 78.6, A). The most sensitive criterion is mediastinal widening, usually larger than 8 cm on an AP view; however, a subjective interpretation of mediastinal widening is more reliable. Other mediastinal abnormalities suggesting mediastinal hematoma secondary to traumatic aortic injury are an obscured aortic knob, loss of the AP window, a displaced nasogastric tube, widened paratracheal stripe, widened paraspinal interface, depression of the left mainstem bronchus, left hemothorax, left apical pleural cap, deviation of the trachea to the right, and multiple rib fractures. The more abnormalities seen on the chest radiograph, the higher the sensitivity in identifying an aortic injury. A normal chest radiograph, however, does not rule out a traumatic aortic injury.

With sensitivity near 100%, a normal CT scan rules out traumatic aortic injury.32 If the results are indeterminate, aortography should be performed. Rarely, a positive helical CT angiogram in a stable patient is followed by aortography for further localization of the injury and identification of other injuries, such as a pseudoaneurysm (see Fig. 78.6, B). Advantages of helical CT angiography over aortography are that it is faster, is noninvasive, requires a smaller volume of contrast agent, and provides information about other thoracic injuries. A high index of suspicion and low threshold for performing screening helical CT angiography are required.

ED, Emergency department.
to save patients with traumatic aortic injury who survive to arrive at the ED.

Transesophageal echocardiography should be performed in unstable patients with suspected traumatic aortic injury but is contraindicated in patients with esophageal injuries. Very high sensitivity and specificity approaching 100% have been reported, but it varies widely depending on operator experience.

Aortography remains the “gold standard” for the diagnosis of traumatic aortic injury. False-positive and false-negative results are rare but do occur. Better sensitivity with helical CT angiography has been reported. Aortography offers improved localization of injury before surgical repair. Newer techniques such as intravenous digital subtraction angiography have improved the speed while reducing the cost of aortography (see Fig. 78.6, C).

A chest radiograph should be obtained in all patients with suspected penetrating great vessel injury, and all wounds should be noted and marked. The examination should be focused specifically on evidence of mediastinal hematoma, hemothorax, foreign bodies near vessels or in the trajectory of a missile, “fuzzy” missiles created by arterial pulsations, and the absence of a missile in patients with a gunshot wound to the chest, which suggests distal embolization. An angiogram should be obtained to further assess the injuries and plan an operative approach in the rare stable patient. With the added benefit of evaluating nearby structures, helical CT angiography will probably replace aortography in the evaluation of stable patients with transmediastinal penetrating injury.13

### TREATMENT

Early orotracheal intubation is required because hematoma expansion can make both orotracheal intubation and creation of a surgical airway impossible. Tracheostomy is contraindicated in patients with great vessel injury involving the upper mediastinum or zone I of the neck because major bleeding can result.

Patients with penetrating great vessel injuries often require ED thoracotomy or immediate thoracotomy in the operating room. In patients with penetrating wounds involving the subclavian vessels, traditional left lateral thoracotomy will often not provide adequate exposure.

Before operative repair of traumatic aortic injury, blood pressure must be controlled, with systolic pressure maintained at 100 to 120 mm Hg to decrease shear stress and progression of the injury. Patients with isolated aortic injuries may be hypertensive and will require short-acting titratable agents such as nitroprusside and esmolol.

### FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Surgical repair of traumatic aortic injury is performed after stabilization of other life-threatening intracranial or intraabdominal injuries. Delayed surgical repair is frequently indicated in elderly patients with multiple comorbid conditions. The mortality rate during surgery is approximately 10%,
and such mortality is primarily related to the extent of the injury and condition of the patient.

**ESOPHAGEAL INJURY**

Esophageal injuries occur infrequently with both blunt and penetrating trauma. More immediate life-threatening injuries often mask the clinical findings, and esophageal leakage can progress to fatal mediastinitis. Esophageal evaluation is indicated in patients with a significant penetrating injury to the neck. The majority of esophageal perforations result from medical endoscopic procedures, not from traumatic injuries.

Penetrating esophageal injury must be considered in any patient with injury near or trajectory through the esophagus. Common mechanisms of penetrating injury include laceration, missile penetration, iatrogenic perforation, and ingested foreign body. Stab wounds to the neck often directly injure the esophagus. High-velocity gunshot result in direct esophageal perforation, as well as delayed necrosis. The majority of penetrating injuries occur at the proximal or distal end of the esophagus during routine endoscopy.

Blunt esophageal injuries are much less common than penetrating injuries. Common mechanisms include crush injuries to the cervical esophagus and barotrauma. Blunt laryngotracheal trauma and cervical spine fractures are associated with injuries to the upper part of the esophagus. Blunt injuries to the lower third of the esophagus occur with sudden increases in intraabdominal pressure against a closed upper esophageal sphincter, analogous to Boerhaave syndrome. The initial rupture typically originates from an inherent weakness in the left posterior aspect of the distal end of the esophagus.

Both cardiopulmonary resuscitation and the Heimlich maneuver have been associated with perforation of the thoracic esophagus. Blast injury can result in primary esophageal injury as a result of the pressure wave, in secondary injury from impact of the patient against fixed structures, and in tertiary injury from blast projectiles.

**PRESENTING SIGNS AND SYMPTOMS**

Typical symptoms of esophageal injury include pleuritic chest pain anywhere along the course of the esophagus, dyspnea, odynophagia, dysphagia, hoarseness, and pain with flexion or extension of the neck. The physical examination should include palpation for subcutaneous emphysema and auscultation for a systolic Hamman crunch produced by mediastinal air.

Commonly, patients have emergency life-threatening injuries that obscure the clinical findings, which can lead to delayed recognition and management. Fever, tachycardia, hypotension, and progressive dyspnea are noted as mediastinitis develops.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

AP or PA chest radiographs should be examined for evidence of mediastinal air, subcutaneous emphysema, left-sided pleural effusion, pneumothorax, and a widened mediastinum. A lateral neck radiograph may reveal prevertebral air displacing the tracheal air column forward. Early in the course of a perforation, radiographic evidence is often minimal. Later CT scans of the chest may demonstrate collections of air or fluid as infection develops, but CT scans are not usually performed for esophageal injury.

Esophagography and esophagoscopy should be performed in all patients with suspected esophageal injury, although neither modality alone is sensitive enough to rule out esophageal injury. The initial esophagography is done with Gastrografin to avoid mediastinal irritation from leakage of barium. Incidentally, a CT scan after barium ingestion may detect small esophageal perforations and small metallic foreign bodies better than plain radiographs can. Negative findings on an esophagogram with Gastrografin enhancement should be followed by the more sensitive barium-enhanced esophagography. Neither contrast agent prevents the use of endoscopy. If findings on both esophagograms are negative, flexible endoscopy can be used to exclude subtle injuries.

**TREATMENT**

Chest tube drainage is often necessary for associated pneumothorax. Persistent air leak is suggestive of esophageal injury. Food particles in the chest tube confirm major injury. Patients should be kept on nothing-by-mouth status. Fluid resuscitation is mandatory. Broad-spectrum antibiotics that cover oral anaerobes should be administered. Placement of a nasogastric tube is controversial because of the risk for mediastinitis and should be done in consultation with trauma or general surgery services.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Management can be operative or nonoperative. Small, minimally symptomatic or chronic perforations, particularly those involving the cervical esophagus secondary to instrumentation, are most amenable to a nonsurgical approach. Consultation with trauma or general surgery specialists for primary surgical repair dramatically improves outcomes.

**DIAPHRAGMATIC INJURIES**

Diaphragmatic injuries are a diagnostic challenge and are associated with significant delayed complications. Complications often develop weeks to years after the initial trauma and consist of symptoms of visceral herniation. Both blunt and penetrating trauma can cause diaphragmatic injuries, but with very different injury patterns. The most common mechanisms for blunt diaphragmatic injuries are MVCs and falls, followed by pedestrian-versus-vehicle collisions, motorcycle accidents, and crush injuries. Penetrating injuries result from gunshot or stab wounds. When detected initially, diaphragmatic injury signals that other severe injuries are probably present.
Gunshot and stab wounds result in injuries to the diaphragm with nearly equal incidence. Stab wounds with a trajectory reaching the 4th intercostal space superiorly or the 12th intercostal space inferiorly must be considered to have perforated the diaphragm and require prudent evaluation. Stab wounds outside this area may also penetrate the diaphragm, depending on the length and angle of the blade. Gunshot wounds anywhere in the neck, chest, abdomen, or pelvis can penetrate the diaphragm. Blunt force to the chest or abdomen often results in large tears in the diaphragm. Left-sided injuries are more common in survivors, whereas an equal incidence of right- and left-sided injuries is noted at autopsy. The negative pressure of inspiration prevents closure and promotes herniation through the wound into the chest cavity. If not detected initially, diaphragm injuries frequently result in visceral herniation months to years later.

**PRESENTING SIGNS AND SYMPTOMS**

Three phases of injury have been described. The acute phase begins with the injury and ends with the initial recovery. A patient with acute diaphragmatic rupture will typically complain of chest pain, abdominal pain, and dyspnea. Findings on physical examination include diminished breath sounds in the lung bases, respiratory distress, bowel sounds in the chest, peritoneal signs, and palpation of viscera during chest tube placement. Large left-sided blunt injuries are more obvious than smaller penetrating and right-sided injuries. Acute diaphragmatic injuries are often overshadowed by other injuries. Frequently, no abdominal tenderness is noted.

In the second, or latent, phase, intermittent herniation of abdominal viscera results in mild and vague symptoms suggesting biliary, gastric, coronary artery, or pulmonary disease. Patients with latent manifestations often appear to have other gastrointestinal or cardiovascular diseases and complain of vague abdominal pain relieved when upright or cough and vague chest pain.

In the last, or obstructive, phase, incarceration, strangulation, and ischemia develop. Additionally, the compressive effects of the intrathoracic bowel on the heart and lung can result in tension enterothorax or viscerothorax. In this phase, symptoms of visceral obstruction, ischemia, and ultimately visceral infarction develop. Herniation should be considered in any patient with vague complaints of chest or abdominal pain and a history of thoracoabdominal trauma.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The initial chest radiograph should be inspected for the classic diagnostic finding, which is a nasogastric tube or viscera in the left hemithorax. Other important but more subtle signs include an indistinct or elevated left hemidiaphragm and left lower lobe atelectasis. Hemopneumothorax is present in 50% of patients with penetrating injury. Up to 25% of patients with penetrating diaphragmatic injuries have normal chest radiographic findings and no abdominal tenderness. CT scanning is 100% specific but only 66% sensitive for the diagnosis of blunt diaphragmatic injury.

In the latent phase of injury, the chest radiograph is typically abnormal. Findings can be subtle, such as a unilaterally elevated hemidiaphragm, unilateral pleural thickening, or basilar atelectasis, or can be significant, such as a shift of the mediastinum or viscera evident above the diaphragm. In cases of delayed herniation, upper or lower gastrointestinal contrast-enhanced studies may be needed to demonstrate herniation (Fig. 78.7).

FAST can also be used in the diagnosis of diaphragmatic rupture. The sonographic features of a ruptured diaphragm include nonvisualization of the spleen or heart, poor diaphragmatic movement, elevated diaphragm, liver sliding sign, pleural effusion, subphrenic effusion, or viscera visualized in the thorax. Traditionally, a diagnostic peritoneal lavage count of less than 10,000 red blood cells/µL is used to rule out a diaphragmatic injury in patients with penetrating thoracoabdominal trauma. Lavage fluid draining from the chest tube is diagnostic. However, diagnostic peritoneal lavage misses up to 25% of diaphragmatic injuries because of bleeding into the chest. Laparoscopy or thoracoscopy is the diagnostic study of choice in patients with high clinical suspicion for diaphragmatic injury not otherwise needing surgery.

**TREATMENT**

A nasogastric tube should be placed carefully in obstructed patients to avoid further trauma to a herniated gastroesophageal
SECTION VIII  TRAUMATIC DISORDERS

juncture. In cases of tension viscerothorax, a chest tube should be placed into the thoracic cavity while taking care to avoid the viscera. The EP should palpate for viscera and diaphragmatic injuries before insertion of a chest tube.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Consultation and admission to trauma or general surgery services is recommended for early surgical repair to prevent delayed complications. Patients with suspected diaphragmatic injuries typically have multiple injuries requiring treatment and hospitalization. An asymptomatic patient with a mechanism for diaphragmatic injury but a negative work-up should be instructed about the need for immediate evaluation if signs of delayed herniation and obstruction develop, such as abdominal discomfort, chest discomfort, shortness of breath, or vomiting.

RED FLAGS

Subtle Life-Threatening Emergencies in the Secondary Survey

Traumatic Aortic Injury
Patients may have no external sign of trauma. Never say “She looks too good to have a traumatic aortic injury,” “It was only a lateral impact,” or “He was wearing a belt and the airbag went off.” The patient will look good until the aorta ruptures; with lateral impact in a moving vehicle collision, there may be increased risk for traumatic aortic injury, and restraints alone do not reduce the risk for traumatic aortic injury.

Esophageal Injury
For any injury near the esophagus, esophagography and esophagoscopy should be performed. Injuries are often subtle until fatal mediastinitis develops.

Diaphragmatic Injury
Penetrating injury anywhere near the diaphragm requires chest radiography, computed tomography, and in some cases, diagnostic peritoneal lavage.

Tracheobronchial Injury
Persistent air leaks despite a functioning chest tube indicate a tracheobronchial injury until proved otherwise. Bronchoscopy must be performed to prevent delayed infection, atelectasis, and loss of lung function.

Liver and Splenic Injuries
Three or more rib fractures or any fracture or tenderness of the sixth rib or below is an indication for abdominal computed tomography to rule out liver and splenic injury.

greater mortality because of multiple related injuries and is associated with trauma patients.2 Blunt trauma is far more common than penetrating trauma in the United States and is associated with trauma patients and consequently has led to an increasingly selective approach to performing explorative laparotomy.

In recent years, management of blunt abdominal trauma has started to change because of the high success rates of more conservative, nonoperative treatment. Such management is a safer, successful, and more cost-effective way to care for these patients and consequently has led to an increasingly selective approach to performing explorative laparotomy.

Abdominal injuries occur in approximately 1% of all trauma patients.3 Blunt trauma is far more common than penetrating trauma in the United States and is associated with greater mortality because of multiple related injuries and greater diagnostic and therapeutic challenges. The mechanism of blunt trauma may range from high-speed injuries to minor falls or direct blows to the abdomen. Motor vehicle collisions are responsible for approximately 75%, blows to the abdomen for approximately 15%, and falls for approximately 9% of injuries.4 Evaluation is further complicated by extraabdominal injuries, as well as by altered mental status from head trauma, alcohol intoxication, or recreational drugs.

### PATHOPHYSIOLOGY

Blunt trauma leads to injury when the elastic limit or breaking point of an organ is exceeded by the impact force applied. Impact force is defined by the amount of energy involved (e.g., the speed of a vehicle, the height of a fall), the location and surface of the blow to the body, and the duration of the impact. Understanding the mechanism of injury is imperative for assessing the initial risk and subsequent evaluation.

The risk for injury may vary slightly according to predisposing factors such as age and gender. Because men are more commonly engaged in dangerous activities, they are more frequently injured than women. A gravid uterus in a pregnant woman may offer some degree of protection to the intraperitoneal structures but adds the unique threat of placental abruption or uterine rupture.

A child’s abdomen is less well protected than an adult’s because of the thinner musculature, and it is far easier to injure abdominal organs such as the duodenum via compression against the posterior vertebrae. The elastic pediatric rib cage also provides less protection to the spleen and liver.

The risk for specific organ injury is linked to its structure and size. In particular, injuries to the spleen are far more common than injuries to other abdominal organs because of its poor elasticity. This is particularly true of abnormal spleens (e.g., patients with mononucleosis); such spleens are injured with far less force because of their larger size, which favors a greater mass effect, and because of their thinner capsule, which lacerates more easily. A spleen can be injured by a minor mechanism such as falling over a chair.

Blunt trauma can lead to injury to any abdominal structure. Direct, focused blows to the epigastrium may result in contusions and even perforation of the duodenum, as well as pancreatic injuries. Deceleration injuries may cause vascular shearing and subsequent thrombosis or tears of the renal artery (grade IV renal injury).
Intraperitoneal bleeding is an immediately life-threatening injury after blunt trauma, and management of intraperitoneal bleeding takes priority over injuries to other systems. Physical examination is unreliable in predicting the presence or absence of injury except for certain high-risk findings such as the seat belt and Kehr signs. Bedside ultrasonography is an excellent initial screening tool that facilitates early triage of patients to either laparotomy or the radiology suite for computed tomography (CT). CT is highly sensitive for detecting solid organ injuries but has lower sensitivity for detecting pancreatic, small bowel, and diaphragmatic injuries. Detailed CT allows grading of organ injuries and nonoperative management of solid organ trauma in stable patients and the use of angiographic embolization in patients with liver, spleen, and renal injuries.

ANATOMY

The abdominal compartment is bounded by the diaphragm, pelvis, and abdominal wall. The boundaries include the vertebral column and the muscles of the abdomen, the most important being the external oblique and rectus. The rib cage below the fourth intercostal space is considered part of the abdominal wall, and thus the abdominal compartment extends up into the chest.

The abdominal compartment is subdivided by the peritoneum into an anterior intraperitoneal cavity and the retroperitoneum. The lack of skeletal protection of the muscular anterior abdominal wall leads to a greater risk for injury to the intraperitoneal organs, notably the spleen, liver, and small bowel. Injured organs in the intraperitoneal cavity may bleed freely because of the substantial fluid capacity of this cavity, whereas brisk bleeding will be contained more by the limited space in the retroperitoneum.

PRESENTING SIGNS AND SYMPTOMS

Certain signs and symptoms suggest the presence of intraperitoneal injury. Blood pressure and heart rate are the most important vital signs when assessing for significant intraabdominal injury. Isolated prehospital hypotension has been shown to be a predictor of mortality and of chest or abdominal injury requiring operative intervention. Prehospital abnormal vital signs should not be discounted even if the patient arrives in a stable condition. Prehospital hypotension in a stable patient is a marker of ongoing intraperitoneal bleeding. Peritonitis, even in the absence of hypotension, is a strong predictor of intraabdominal injury, although it does not necessarily predict the need for laparotomy in a stable patient.

Physical examination is limited in its ability to identify the presence or absence of intraabdominal injury. Therefore, further diagnostic testing should be performed, despite minimal clinical findings, if the abdomen sustained significant direct trauma such as a baseball bat or handlebar injury or if the patient is difficult to evaluate because of concomitant injuries or altered mental status for any reason. Other significant mechanisms, such as a rollover motor vehicle collision, a motor vehicle collision with ejection or significant intrusion, or a substantial fall, should be evaluated in light of the patient’s clinical picture. A motor vehicle collision with steering wheel deformity is associated with serious abdominal injury in front seat passengers but not in drivers; direct impact from a bicycle handlebar suggests an increased likelihood of abdominal injury requiring laparotomy. Intraabdominal injury can also result from minor mechanisms, such as a fall from the standing position onto the abdomen.

Several insensitive clinical signs suggest specific injuries in a blunt trauma patient. The Kehr sign, which is left shoulder pain, suggests splenic rupture. The Cullen sign is ecchymosis around the umbilicus, and the Turner sign is ecchymosis in the flank area. These signs suggest retroperitoneal hemorrhage but are very rarely found in acute trauma patients. They occur only hours after injury and thus are of little use in the initial assessment of patients who have sustained blunt abdominal trauma.

The presence of the seat belt sign (erythema, ecchymosis, or abrasions in the pattern of a seat belt) is associated with intraperitoneal injuries—specifically, pancreatic, hollow viscus, and mesenteric injuries. Multiple studies have shown a significantly higher incidence of intraabdominal operative pathology in patients with the seat belt sign than in those lacking this sign after motor vehicle trauma. The seat belt sign usually results from incorrect use or improper placement of a seat belt restraint. It should be used as a predictor of intraperitoneal injury and therefore as an indication to perform diagnostic imaging in patients with blunt abdominal trauma. Negative findings on computed tomography (CT) in a patient with abdominal tenderness and the seat belt sign should be followed by observation, diagnostic peritoneal lavage (DPL), or laparotomy, depending on the findings and clinical suspicion. Although evisceration and clear-cut peritonitis are diagnostic of intraabdominal pathology, neither is a common finding.

Abdominal tenderness is often absent in patients with intraperitoneal injury. Drugs, alcohol, hypotension, and the presence of head injury reduce the patient’s ability to sense pain or tenderness. Additionally, other significant injuries such as fractures or large lacerations may distract the patient from feeling the pain associated with abdominal injury. In a large prospective study, 19% of patients with positive findings on CT for intraabdominal injury did not have abdominal tenderness. Other studies have reported abdominal tenderness in only 42% to 75% of patients with small bowel or mesenteric injury. The sensitivity, specificity, and negative and positive predictive values of abdominal pain or tenderness in predicting intraabdominal injury are reported to be 82%, 45%, 93%,
and 21%, respectively. Furthermore, patients with chest wall injuries and pneumothorax are at risk for injury and may not exhibit abdominal pain or tenderness. Thus, it is important to avoid relying solely on the physical examination, especially in a multitrauma patient or one with altered mental status, when deciding whether to perform diagnostic testing on a patient after blunt abdominal trauma.

**EVALUATION**

Physical examination of the abdomen following trauma consists of observation and palpation. The abdomen should be observed for signs of disruption, evisceration, ecchymosis, abrasions, and distention. Although it is important to perform a rectal examination to assess rectal tone and the prostate for possible urethral injury, a positive stool guaiac test is not predictive of injury. If gross blood is present on rectal examination, large bowel or rectal injury should be suspected.

**RED FLAGS**

- Prehospital hypotension indicates the need for diagnostic imaging of the abdomen.
- Abdominal ecchymosis is predictive of intraperitoneal injury.
- The presence of a Chance fracture is predictive of intraperitoneal injury.
- Left shoulder pain suggests splenic injury.
- Low rib fractures are associated with liver and spleen injuries.

The initial physical examination includes assessment of the pelvis for stability and the urethral meatus for blood as an indicator of associated urethral injury. These aspects of the examination will help the emergency physician (EP) plan the subsequent evaluation. Patients with pelvic instability may need stabilization of a pelvic fracture and embolization, whereas those with a urethral injury may need retrograde urethrography and suprapubic placement of a Foley catheter.

**DIFFERENTIAL DIAGNOSIS**

The specific injuries to be concerned with after blunt abdominal trauma can be broken down into several categories: solid organ (liver and spleen), hollow viscus, mesenteric, vascular (inferior vena cava and aorta), diaphragmatic, and retroperitoneal (renal, bladder, pelvic fractures, and vascular). Other less common injuries are gallbladder, pancreas, and rectus sheath hematomas.

**CHANCE FRACTURES**

A single lap belt restraint can result in Chance fractures of the lumbar spine. In a recent report, 33% of patients with Chance fractures had associated intraabdominal injury, and of these patients, 22% had hollow viscus injuries. In other studies, up to 89% of patients with Chance fractures had small bowel injuries. Some centers consider the presence of Chance fractures and the seat belt sign to be an indication for exploratory laparotomy.

**UPPER ABDOMINAL INJURIES**

Low rib injuries may be associated with spleen or liver trauma, as well as kidney injuries. The incidence of splenic injury in patients with “isolated” low rib pain or tenderness (no abdominal tenderness) was 3% in a recent report. Although the only prospective study on the subject is not definitive, it suggests that patients with pleuritic pain and isolated low left rib pain or tenderness, regardless of whether abdominal tenderness is present, should undergo imaging. In addition, patients with abdominal tenderness following low chest trauma should undergo diagnostic imaging (e.g., CT).

**LOWER ABDOMINAL INJURIES**

Blunt abdominal trauma may result in retroperitoneal injury to the kidneys or ureters. Intraperitoneal or extraperitoneal bladder rupture may also occur. Major pelvic fractures are associated with abdominal injuries in 30% of patients. Injury to the abdominal aorta is rare after blunt abdominal trauma. Other less serious injuries are abdominal wall hematomas, which do not usually require operative intervention but can result in significant blood loss.

**INJURIES WITH DELAYED PRESENTATION**

Several injuries are notoriously seen in delayed fashion or have subtle clinical findings. Pancreatic injuries may be manifested as abdominal pain and tenderness several hours after the trauma. Duodenal hematomas typically become evident 5 to 7 days after the trauma as vague abdominal pain and vomiting. This is in contrast to patients with duodenal perforations, who usually have acute pain and tenderness immediately after the trauma.

Traumatic diaphragmatic hernia can also occur in delayed fashion. These injuries are frequently missed because the sensitivity of CT for diaphragmatic injuries is low and the majority of patients have associated injuries. Most of these injuries result from a vehicular collision. Because the right hemidiaphragm is protected by the liver, the left hemidiaphragm is more commonly involved.

Diaphragmatic injuries occur in three phases. In the acute phase, immediately after injury, patients may have decreased or absent breath signs on one side of the chest or bowel sounds in the chest. If the injury is not detected, patients may go through a latent phase consisting of intermittent visceral herniation into the chest through the diaphragmatic rupture. These patients may have vague postprandial abdominal pain (which improves with standing because the herniated bowel is reduced), nausea, vomiting, and belching. During this phase the injury can go undetected for months to years. With time, patients will eventually enter the obstructive phase, which is associated with herniation and incarceration of bowel, intestinal obstruction, and ischemia. These patients exhibit abdominal pain, distention, and vomiting.

In the acute setting, patients with a diaphragmatic injury can also have tension viscerothorax—herniation of bowel into the chest, which results in increased intrathoracic pressure and mediastinal shift with compression of the superior vena cava. These patients have hypotension and decreased breath sounds on the affected side of the chest.
SOLID ORGAN INJURIES

The most common type of injury is solid organ injury. More than 90% of the injuries sustained in blunt trauma are isolated to the liver and spleen. Patients with hypotension as a result of blunt trauma usually have free rupture of a solid organ. Delayed onset of symptoms or pain without hypotension should raise concern about encapsulated hepatic or splenic trauma or hollow viscus injury. Although most intraperitoneal injuries today are managed nonoperatively, delayed diagnosis in some cases can lead to severe morbidity or mortality. Free intraperitoneal bleeding is the most urgent diagnosis in patients with blunt abdominal trauma. This immediately life-threatening condition may require interventions, including transfusion, exploratory laparotomy, and angiography with embolization.

Diagnostic Peritoneal Lavage

Some authors take a conservative approach and recommend confirming the results of negative ultrasonography with DPL in hypotensive patients. If ultrasonography is unavailable or if the results are indeterminate, DPL is required to determine the presence of intraperitoneal bleeding as an indication for immediate laparotomy. Before performing DPL, the EP should place a nasogastric tube and Foley catheter to decompress the stomach and drain the bladder.

DPL involves placement of a catheter into the peritoneal space and aspiration with a 10-mL syringe to see whether blood is present. In an unstable patient, an initial aspirate of 10 mL of blood is an indication for laparotomy. The presence of bile, food particles, or other gastrointestinal contents is also considered an indication for laparotomy. If the aspirate is negative, other sources of bleeding should be addressed (e.g., pelvic fractures). One liter of normal saline should be instilled into the abdomen if the initial aspirate is negative and then drained from the abdomen and sent to the laboratory for analysis.

THE UNSTABLE PATIENT

INITIAL MANAGEMENT

The initial therapeutic intervention in patients with presumed intraperitoneal injury is to address the ABCs of trauma (airway, breathing, and circulation). Initially, all patients should receive high-flow oxygen. Intubation should be performed on unstable or severely injured multitrauma patients or those with the potential for rapid decline. After breathing is attended to, circulatory status is addressed. Antecubital venous or central line access should be obtained.

IMMEDIATE OPERATIVE INTERVENTION

There are several indications to proceed immediately to the operating room without further diagnostic testing, including evisceration, gross blood per rectum, blood per nasogastric tube or hematemesis, evidence of diaphragmatic injury, and hemodynamic instability with evidence of intraperitoneal injury (e.g., positive ultrasound findings).

Focused Abdominal Sonography for Trauma

Bedside ultrasonography has many advantages as an initial triage tool in an unstable trauma patient. It is readily accessible at most level I trauma centers and, in the hands of trained EPs, is accurate in detecting hemoperitoneum. Focused abdominal sonography for trauma (FAST) can be performed in less than 2 minutes and can triage patients to the operating room or further diagnostic testing, depending on the patient’s stability. In trauma patients, the incidence of an indeterminate sonographic result is low (less than 7%), and the reported sensitivity and negative predictive value in unstable patients approach 100%. The presence of hemoperitoneum in an unstable patient is an indication for operative intervention. The only caveat is that in patients with major pelvic trauma who may have bladder rupture with uroperitoneum, diagnostic peritoneal aspiration may be indicated to distinguish blood from urine. If the sonographic findings are negative, other sources of bleeding should be addressed, such as pelvic fractures and retroperitoneal bleeding.

THE STABLE PATIENT

LABORATORY TESTING

Laboratory tests are rarely helpful in the initial resuscitation of patients after blunt abdominal trauma. The utility of ordering individual laboratory tests when a specific clinical need is present versus routinely ordering a standard “trauma panel” has been studied. A significant cost savings, without adverse events, occurs if this practice is followed. Several laboratory tests are useful in the initial evaluation of blunt trauma patients. The hematocrit should be measured for use as a baseline value and may be helpful as an indicator of bleeding if it is very low. Patients with a high likelihood of requiring an operation should have their blood typed and cross-matched in the event that a transfusion is required. A bedside glucose test should be performed on patients involved in a single-car accident and in patients with altered mental status after trauma.

All women of childbearing age should undergo a pregnancy test and be questioned about whether they are pregnant. Serial ultrasonography can be used as the initial and often definitive modality, and CT should be used sparingly in the first 20 weeks of gestation to avoid unnecessary exposure to radiation.
Coagulation profiles should be performed in patients with a significant mechanism of trauma and in those who will probably require an operation. In addition, any patient receiving warfarin (Coumadin) therapy should have a coagulation profile performed.

Lactate levels and base excess are two laboratory tests that have been shown to predict bleeding. In one recent study of stable trauma patients, an increased lactate level (>2.5 mmol/L in ethanol-negative patients and >3 mmol/L in ethanol-positive patients) and an increased base deficit (>0.0 in ethanol-negative patients and >3.0 in ethanol-positive patients) were associated with a significant risk for torso injury, whereas patients with a normal base deficit were unlikely to have injury. Other authors consider a base deficit cutoff value of 6 or less to be predictive of intraabdominal injury and an indication for diagnostic imaging or DPL.

Urinalysis should be performed in all blunt trauma patients with a significant mechanism of injury. The presence of gross hematuria is an indication for evaluation of the genitourinary tract. Microscopic hematuria is a sign of mild renal injury that does not require treatment; its presence in a stable patient without a significant deceleration injury (associated with renal pedicle injury) is not an indication for additional diagnostic imaging. Some evidence also suggests that microscopic hematuria consisting of 25 or more red blood cells per high-power field may be one of the predictors of intraperitoneal injury.

Amylase and lipase levels do not predict pancreatic injury in the acute setting. However, they may be helpful for detecting traumatic pancreatitis in patients initially evaluated hours after trauma.

**PLAIN RADIOGRAPHS**

Plain radiographs cannot rule out intraperitoneal injury after blunt trauma. Chest radiography may be used to diagnose a diaphragmatic rupture (Fig. 79.1). However, plain radiographs of the chest are diagnostic of diaphragmatic rupture in only 50% of patients with left-sided rupture and in only 17% of those with right-sided rupture. Free air is a rare finding on an upright chest radiograph that indicates hollow viscus rupture (stomach or colon), but upright chest radiography is not usually feasible after blunt trauma. Thus, plain radiographs should not be used to rule out intraperitoneal injury.

Radiotherapy is also useful for detecting pelvic fractures as a cause of hypotension after blunt trauma and can help guide evaluation for the management of associated genitourinary injuries. Although pelvic radiography is not necessary in patients with normal mental status and no pain or tenderness, it should be performed in unstable or seriously injured patients with an appropriate mechanism of injury.

**ULTRASONOGRAPHY**

FAST is recommended for all blunt trauma patients with any significant mechanism of injury as an initial screening test regardless of patient stability. Ultrasonography is now listed in the advanced trauma life support algorithm for abdominal trauma and is used in the majority of level I trauma centers. In the blunt trauma setting, ultrasonography has become part of the secondary survey to detect hemoperitoneum as an indicator of intraperitoneal injury.

If the sonogram shows free fluid and the patient is hemodynamically unstable, exploratory laparotomy is indicated. A stable patient with free fluid should undergo CT immediately to identify the type of injury and determine the need for laparotomy. A clinical algorithm that incorporates FAST is presented in Figure 79.2.

FAST is also used for the rapid detection of pericardial fluid, hemothorax, and pneumothorax. It does not replace chest radiography for hemothorax and pneumothorax but may be obtained faster and can be used to expedite thoracostomy tube placement.

The major limitation of ultrasonography is its inability to identify or grade solid organ injury. Its sensitivity for detecting hemoperitoneum as an indicator of intraperitoneal injury ranges from 76% to 90%, and its specificity ranges from 95% to 100%. However, its sensitivity is as low as 33% with splenic injuries and 12% with hepatic injuries for identifying encapsulated solid organ bleeding. Ultrasonography is also limited in assessing injuries that are not associated with a large amount of hemoperitoneum, such as retroperitoneal bleeding and injuries to the small bowel or diaphragm. Up to one third of patients with intraperitoneal injury will have negative findings on FAST, including as many as 10% of patients who require surgery. Thus, FAST does not replace more definitive tests such as CT, but it can be a triage tool to expedite the evaluation and management of patients with blunt abdominal trauma. The amount of intraperitoneal fluid that must be present to have abnormal FAST findings is at least 150 mL and may be as much as 1 L.

The technique of bedside ultrasonography in trauma patients consists of four standard views (Fig. 79.3): right upper quadrant (Morison pouch), subxiphoid, left upper quadrant, and suprapubic (pouch of Douglas). Although this examination has no standard sequence, the suprapubic view takes advantage of the full bladder as a sonographic window and should therefore be obtained before placement of a Foley catheter. Most operators start with the Morison pouch view because it is technically the easiest.

Obtaining all the views rather than one single view increases the sensitivity of the test. Performing serial examinations every 30 minutes into the resuscitation—or if a change in clinical status occurs—increases the sensitivity further. Trendelenburg positioning may improve the sensitivity by causing the hemoperitoneum to pool in dependent spaces. The differential diagnosis for fluid seen on ultrasonography includes...
ultrasonography. Currently, DPL is indicated when ultrasonography is unavailable or if the results are indeterminate in an unstable patient. Some authors recommend DPL to confirm the absence of hemoperitoneum in unstable patients with negative results on ultrasonography.

DPL is very sensitive in detecting intraperitoneal bleeding, can be performed rapidly, and is inexpensive. It can detect small amounts of intraperitoneal blood (as little as 20 mL).

The accuracy of DPL for predicting or ruling out intraperitoneal bleeding is close to 98%. DPL has, however, been shown to be less accurate in patients with major pelvic fractures. The false-positive rate may be higher in this group of patients because of the presence of uroperitoneum as a result of bladder injury. Consequently, in the presence of a pelvic fracture, diagnostic peritoneal aspiration may be indicated to determine whether a positive FAST result is due to blood or urine.

All rights reserved.)

**Fig. 79.3** Focused abdominal sonography for trauma: four views.

**Fig. 79.4** Morison pouch showing fluid (arrowheads) in the space between the liver and the right kidney.
The disadvantages of DPL are that it is invasive, does not identify the specific organ that is injured, and does not sample the retroperitoneal space. It will also detect small amounts of bleeding associated with injuries that do not require operative intervention. The nontherapeutic laparotomy rate for patients with a positive DPL finding is reported to be as high as 35%. 23 Thus, in stable patients, a positive DPL result is not an indication for laparotomy.

The only absolute contraindication to DPL is a clear need for emergency laparotomy. Relative contraindications include morbid obesity, previous abdominal surgery (because of the presence of adhesions), and late-term pregnancy.

DPL findings that predict the presence of intraperitoneal injury after blunt trauma are a red blood cell count greater than 100,000/mm³, a white blood cell count greater than 500/mm³, amylase level greater than 10 IU/L, and alkaline phosphatase level of 3 IU/L or greater. The complication rate for DPL is less than 1%. The most serious complication is bowel perforation; other complications include wound infection and bleeding.

**COMPUTED TOMOGRAPHY**

Abdominal and pelvic CT is the standard diagnostic imaging modality for a stable patient with possible intraabdominal injury. CT provides excellent detail of solid organ and retroperitoneal injuries. Its performance in diagnosing hollow viscous injuries continues to improve. Because of the accuracy and detail of CT images, nonoperative management of solid organ injury can now be performed safely. With the use of three-dimensional reconstruction, radiologists can also image the lumbar spine and pelvis to evaluate for fractures.

The disadvantages of CT are the difficulty in monitoring and resuscitating a patient in the radiology suite and the risk for contrast allergy and renal failure from administration of the dye. The complication rate is 3%, which includes aspiration of oral contrast material.

CT is indicated in stable patients when intraabdominal injury is clinically of concern because of abdominal wall findings, traumatic distracting injuries, and a significant mechanism of injury. The presence of distracting injury and the need for operative intervention for other injuries (e.g., orthopedic injuries) are also indications for performing CT. In awake patients who have a reliable abdominal examination and no abdominal tenderness, the yield of performing abdominal CT scanning because they are undergoing extraabdominal surgery is very low. Less than 2% of patients undergoing abdominal CT scanning only because of the need for general anesthesia for urgent extraabdominal surgery actually had an abdominal injury, and less than 0.5% required laparotomy.38,39

Recent studies have looked at determining clinical predictors for identifying patients at low risk for intraperitoneal injury after blunt trauma who may not need CT. One such clinical prediction rule consists of a Glasgow Coma Scale score of less than 14, costal margin tenderness, abdominal tenderness, femoral fracture, hematuria consisting of greater than 25 red blood cells per high-power field, hematocrit of less than 30%, and abnormal chest radiograph findings (pneumothorax or rib fracture). In the absence of any of these clinical variables, patients are at very low risk of having intraperitoneal injury (96% sensitivity and 99% negative predictive value).35

Many trauma centers in the United States and Europe are using a newer technique, the “pan scan,” for obtaining a rapid CT scan of the head, neck, and torso in patients with a high mechanism of trauma who are at higher risk for traumatic injuries. The advantage of this technique is that it is faster than performing segmental, sequential CT scans and may detect injuries that would otherwise be missed or diagnosed in delayed fashion, such as spine and chest injuries. The biggest risk, however, is that this technique will be overused and expose patients to unnecessary radiation and cancer risk. The exact indications for performing a pan scan are controversial. However, a conservative approach would be to obtain a pan scan in patients with a major traumatic mechanism who are also not evaluable because of head injury, intubation, or depressed mental status from alcohol. A pan scan is also recommended for elderly trauma patients who may sustain significant injuries with lesser mechanisms and for patients with prehospital hypotension who are stable in the emergency department because they are also at risk for torso trauma.40,41

Determining when a patient is stable enough to undergo CT remains a point of controversy. An unstable patient should not be sent to the radiography suite, where it is difficult to monitor and resuscitate a sick patient. Most centers use the response to fluid resuscitation and transfusion as an indicator of whether the patient is stable enough to be transferred to the radiography suite for CT. This decision may also be influenced by the proximity and type of CT scanner.

CT is very accurate in diagnosing intraperitoneal injury, especially for detecting solid organ injury, as stated previously. Another advantage of CT is its higher accuracy and sensitivity than plain radiographs for detecting fractures of the thoracolumbar spine (TLS). In one prospective study, the accuracy of CT of the torso for detecting TLS fractures was 99% versus 87% for plain radiographs, with the “gold standard” for fracture being the discharge diagnosis of acute fractures confirmed by thin-cut CT or clinical examination of the patient when alert (or both). It is also much faster to obtain a torso CT scan than it is to obtain multiple plain radiographic spine images.42

The limitations of CT lie in its low sensitivity for diaphragm, mesenteric, hollow viscous, and pancreatic injuries. Although the newer-generation multidetector CT scanners appear to have better resolution and sensitivity for these rare injuries, they are still not highly accurate. The sensitivity for diaphragmatic injury is between 67% and 84%, with specificities reported to be between 77% and 100%.12,43-46

The sensitivity of CT for detecting hollow viscous injury is reported to range from 83% to 94%.50,51,52-55 Multidetector CT without oral contrast enhancement was 82% sensitive and 99% specific for detecting bowel and mesenteric injuries.51 The reported sensitivity of CT for detecting pancreatic injuries after blunt trauma ranges from 50% to 68%, even with spiral CT technology.52,53 The use of oral contrast is not associated with an increase in sensitivity for detecting pancreatic injury.53 In a recent multicenter study, the sensitivity of CT was 76% for pancreatic injuries and 70% for duodenal injuries.54

**Oral Contrast or No Oral Contrast?**

An ongoing controversy on the use of CT scanning for blunt abdominal trauma is the utility of oral contrast versus
intravenous contrast alone. Oral contrast is associated with increased time and the potential for vomiting, aspiration, and other complications, as well as discomfort if a nasogastric tube is placed. Several studies have documented that oral contrast enhancement is not essential for identifying solid organ, mesenteric, or bowel injuries. Because use remains controversial and local customs often prevail, oral contrast agents are still commonly used in many trauma centers.

**Findings in Patients with Blunt Abdominal Trauma**

CT findings suggesting solid organ injury are disruption of the parenchyma, extravasation of contrast material, and hemoperitoneum. Patients with blunt intestinal or mesenteric injuries may have more subtle findings such as free fluid without obvious organ injury, mesenteric stranding or edema, and bowel wall hematoma. Other indicators of bowel and mesenteric injury are pneumoperitoneum, tears in the bowel wall, and wall thickening.

Isolated intraperitoneal fluid in patients without solid organ injury is associated with a high incidence of bowel or mesenteric injury. In patients without solid organ injury and with more than trace amounts of free fluid, the therapeutic laparotomy rate is 54% to 94%. At surgery, small bowel, mesenteric, and diaphragm injuries are usually found.

**ANGIOGRAPHY**

When combined with embolization, angiography is both a diagnostic and therapeutic modality. Though classically used in blunt trauma for the treatment of pelvic fractures, it has been found to be especially helpful in the nonoperative treatment of active bleeding from solid organ injuries. High-grade spleen and liver injuries, as well as renal lacerations, are amenable to this technique. Patients selected for this procedure must be stable and have solid organ injuries with active extravasation (contrast blush) on abdominopelvic CT.

**TIPS AND TRICKS**

Do not underestimate the mechanism of injury. A significant mechanism of injury requires evaluation for intraperitoneal injury even if the patient is stable and the findings on physical examination are normal.

The presence or absence of abdominal tenderness does not predict intraperitoneal injury.

Alcohol and distracting injuries can make the findings on physical examination unreliable.

All blunt abdominal trauma patients should undergo FAST. Before performing DPL, place a nasogastric tube and Foley catheter and obtain a pelvic radiograph.

Positive FAST findings or DPL aspirate in an unstable patient is an indication for laparotomy.

Unstable patients should not be transferred to the radiology suite for CT.

Significant intraperitoneal fluid without solid organ injury on a CT scan suggests the presence of small bowel injury. CT can fail to identify injuries of the pancreas, diaphragm, small bowel, and mesenterium.

**TREATMENT**

The initial treatment of patients with blunt abdominal trauma includes fluid resuscitation, transfusion, and simultaneous consultation with the trauma surgery facility for operative intervention, angiography, or admission for observation.

Intravenous fluid resuscitation with normal saline or lactated Ringer solution is indicated for patients who are hemodynamically unstable (tachycardia or hypotension). The optimal amount and goal of resuscitation are controversial. Although the standard has been to immediately infuse 2 L of crystalloid followed by blood transfusion in patients with continued instability, many institutions move rapidly to blood transfusion and limit resuscitation so that patients are kept “underresuscitated” with a systolic blood pressure of approximately 90 mm Hg. This can usually be accomplished with type O-negative blood in women of childbearing age and type O-positive in all others. Once the bleeding lesion is identified and definitively controlled, full resuscitation is instituted. However, this practice is not typically recommended for patients with possible traumatic brain injury.

The presence of an unstable pelvis on physical examination or on the initial pelvic radiograph is another indication for early blood transfusion because patients with this condition will bleed profusely. EPs should place a pelvic stabilization binder or simply wrap a sheet tightly around the pelvis to stabilize the fractures as an early intervention.

For patients requiring large amounts of blood products, new evidence suggests that early administration of plasma and a higher ratio of plasma to packed red blood cells (PRBCs) transfused will result in lower mortality rates. In patients who require massive transfusion (defined as 10 or more units of PRBCs in 24 hours), it is recommended that they receive plasma, platelets, and PRBCs in a ratio close to 1:1:1.

Indications for operative intervention include hemodynamic instability, diaphragmatic injury, and hollow viscus injury. Although high-grade spleen and liver injuries once routinely underwent surgery, the use of angiography with embolization has become more common. Other CT findings that trauma surgeons may consider indications for operative intervention include the presence of intraperitoneal fluid without obvious organ injury and evidence of active extravasation. Because of the high incidence of associated small bowel injury, many institutions consider the presence of a Chance fracture in conjunction with abdominal wall ecchymosis an indication for laparotomy.

**PRIORITIZING MANAGEMENT OF INJURIES**

Emergency department management of unstable patients with blunt abdominal trauma becomes challenging when associated injuries are present. In general, intraperitoneal bleeding trumps other injuries in terms of the immediate need for operative management. An unstable patient with known intraperitoneal hemorrhage and associated pelvic trauma should undergo laparotomy first, followed by management of pelvic injuries (e.g., angiographic embolization of pelvic vessels). In
unstable patients with evidence of associated traumatic brain injury, neurosurgical consultation should be obtained for intracranial bolt placement in the operating room while the intraperitoneal injuries are being addressed. Suspicion of aortic injury presents an added challenge in management. The aortic injury is not usually the cause of hemodynamic instability, and intraperitoneal bleeding should be the presumed source of the hypotension. Thus, in patients with concomitant aortic and abdominal injuries, laparotomy should be performed first. Abdominal bleeding takes priority over orthopedic injuries; frequently, however, the trauma surgeon can perform laparotomy at the same time that the orthopedic surgeon is repairing an open fracture.

NONOPERATIVE TREATMENT
Many reports in the surgical literature document success with nonoperative management of patients with spleen and liver lacerations.63 Most centers, however, consider the presence of hemodynamic instability or transfusion requirements as indications to operate on patients with solid organ injuries. Age may also be used as an indicator for surgery; children do well with nonoperative management, whereas elderly patients may have lower success rates with nonoperative care. Nonoperative salvage rates in patients with lacerations of the spleen are 94%, and up to 80% of grade 4 and 5 splenic injuries can be managed successfully without operative intervention.64

In one prospective study, the failure rate of nonoperative treatment of kidney, liver, and splenic lacerations was 22%; the failure rate was higher for splenic injury than for liver or kidney injuries.65 Independent predictors of failure of nonoperative management were fluid identified on screening ultrasonography, significant blood on CT (>300 mL), and the need for blood transfusion.65

INTERVENTIONAL RADIOLOGY
In major trauma centers, interventional radiologists in conjunction with trauma surgeons are performing angiography with embolization instead of operative management. The nonoperative salvage rate in patients with splenic lacerations who undergo embolization is 90%.64 Angiography with embolization may be performed in patients who are hemodynamically stable and do not have associated hollow viscus or other injuries requiring operative intervention.66,67

For splenic injuries, arterial embolization may be indicated for patients with active extravasation of contrast material, pseudoaneurysm or arteriovenous fistula, large hemoperitoneum, and a higher grade of injury (III to V), assuming that no indications for operative intervention are present. The combination of contrast blush and significant hemoperitoneum may also predict a high failure rate for nonoperative management and may be an indication for arterial embolization or laparotomy with splenectomy.68

If the patient is initially transported to a hospital that is not a designated trauma center, the EP must decide when to transfer the patient to the trauma center and what tests to perform before transfer. If the trauma is isolated to the abdomen and a general surgeon is available to admit the patient or perform therapeutic laparotomy, transfer may not be necessary. Patients with multisystem trauma or hemodynamic instability require transfer to a trauma center.

Penetrating Abdominal Trauma

Eric L. Legome and Carlo L. Rosen

KEY POINTS

- Patients with diffuse peritonitis or hypotension after penetrating abdominal trauma require immediate operative intervention.
- Conversely, mandatory laparotomy for all wounds that penetrate the anterior abdominal fascia is no longer the sole approach.
- Evaluation of patients with stable penetrating trauma depends on the anatomic site of injury, the weapon used, serial examinations, and local diagnostic and surgical resources.

EPIDEMIOLOGY

Since the 1960s, U.S. mortality rates of 9.5% to 12.7% for civilian gunshot wounds and up to 3.6% for stab wounds have been reported. Most deaths caused by penetrating trauma take place in the first 24 hours; about 70% occur in the first 6 hours of the patient’s course, most commonly in the emergency department (ED), followed by the operating room. Most of these patients tend to have vascular injuries and succumb to exsanguination or refractory hemorrhagic shock. If patients survive the first 24 hours, later deaths tend to cluster after 72 hours and are related mainly to acute systemic complications such as multiple system organ failure, acute respiratory distress syndrome, pulmonary embolism, and pneumonia. Management of penetrating abdominal trauma has undergone many changes over the last 20 years. Major transformations include rapid transport to trauma centers, “scoop and run” protocols in the field, damage control surgery, increased use of interventional radiologic techniques, and recognition and treatment of abdominal compartment syndrome. Better diagnostic studies, including rational use of computed tomography (CT) and ultrasonography, as well as expanded use of laparoscopy, have also improved morbidity rates, but no marked change in mortality has occurred. Although management of patients with obvious peritonitis or hypovolemic shock remains essentially unchanged from the perspective of the emergency physician (EP), a patient without obvious intraperitoneal injury still presents a diagnostic dilemma. The benefits of nonoperative management, when performed appropriately, include lower hospital costs, less morbidity, and shorter hospital stays.

PATHOPHYSIOLOGY

Physiologic evaluation of patients with penetrating abdominal trauma concentrates on two major findings related to the pathophysiologic basis of the injury—peritonitis and hemodynamic instability. Peritonitis develops when the peritoneal envelope and the posterior aspect of the anterior abdominal wall are inflamed by enteral contents. Intraperitoneal or retroperitoneal blood and organ contents inflame the deeper nerve endings (visceral afferent pain fibers), thereby resulting in poorly defined and localized pain. Direct contact of the parietal peritoneum with blood or bowel contents can cause inflammation, which may be manifested as tenderness on palpation of the abdomen, as well as involuntary guarding of the abdominal wall musculature. Patients may also have referred pain. Because of the afferent, embryologically related pain fibers that ascend during development, a back or shoulder distribution of pain may provide a clue to the damaged organ (e.g., left shoulder pain from splenic rupture with subphrenic blood). Even though penetrating trauma is associated with multiple specific mechanisms, for most purposes it is divided into low- and high-energy injury; in general, these categories correlate with stab wounds or gunshot wounds. Gunshot wounds may be further divided into low- and high-velocity injuries, although both have the ability to cause secondary injury by energy transfer, fragmentation, and secondary missiles such as bone fragments. Handguns and lower-caliber rifles such as .22 gauge tend to have lower energy transfer than do military rifles and hunting rifles. Shotgun injuries, despite having lower velocity, often cause massive tissue damage if the wound is sustained at close range (i.e., less than 3 feet).

PRESENTING SIGNS AND SYMPTOMS

The anterior part of the abdomen is the region between the anterior axillary lines from the anterior costal margins to the groin. The thoracoabdominal area is the region in which an injury can enter the chest, abdomen, or both. In addition to the anterior abdominal boundaries, it includes the lower part of the chest bordered by the nipple line or the fourth intercostal space anteriorly, the sixth intercostal space laterally, and the inferior scapular tip posteriorly because the diaphragm may extend to this level with expiration. The flank is the area between the anterior and posterior axillary lines bilaterally and ranges from the sixth intercostal space to the iliac crest. The back is bordered by the posterior axillary lines, with the inferior scapular...

Classic teaching is that the majority (about 90%) of gunshot wounds to the abdomen penetrate the peritoneum. However, recent studies looking at nonoperative management show that a larger number of nontangential wounds do not penetrate. If a patient is initially stable and peritoneal signs are absent, the rate is probably closer to about 40%; however, abdominal gunshot wounds associated with peritonitis or instability have penetrated the peritoneum. The majority of wounds that penetrate the peritoneum require laparotomy for repair. The most commonly injured organs are the small bowel, colon, and liver, followed by vascular structures, the stomach, and the kidneys (Box 80.1).

Stab wounds, as opposed to gunshot wounds, tend to follow the track of the wound and have more predictability. Approximately one fourth to one third of anterior abdominal stab wounds penetrate the peritoneum. Of those that do penetrate, about one third cause intraabdominal injury that requires operative repair. In addition to wounds involving the abdominal cavity, injuries to the thoracic cavity must also be considered in patients with thoracoabdominal stab wounds or any gunshot wound.

Physical examination often plays a major role in the management of patients with penetrating abdominal trauma, especially those who are hemodynamically stable. Serial examinations are a common and time-tested management strategy for low-velocity wounds. Studies show that it is an effective approach and that delay in diagnosis, if less than 24 hours, does not lead to a significant increase in complications. Furthermore, the decrease in morbidity and cost of nontherapeutic laparotomy is considerable. In fact, in some centers, even patients with evisceration (especially omentum alone) without peritonitis are observed successfully after replacement of the eviscerated peritoneal contents, although such management remains controversial.

Differential Diagnosis and Medical Decision Making

Examination may be used as a sole modality or in conjunction with other modalities. In patients with an anterior stab wound, local wound exploration can be a valuable diagnostic aid and should shorten a prolonged evaluation or observation if the results are negative. Its utility is dependent on the wound’s mechanism and location. Stab wounds involving the anterior aspect of the abdomen are well suited for local wound exploration because many do not penetrate the fascia and can easily be visualized. Back, flank, and thoracoabdominal wounds do not allow clear delineation of the wound track and extent and are not candidates for this procedure. Likewise, this is a poor option for gunshot wounds or wounds from a sharp pinpoint instrument (e.g., ice pick).

Over the last decade, patients with gunshot wounds have also been managed by serial observation, though generally in conjunction with some other modality, usually CT. The length of observation varies by institution. Standard practice is usually a 24-hour observation period, but recent data suggest that all important injuries will become apparent within a 12-hour period. Until more data are available or a clear institutional protocol has been established, approximately 24 hours of observation seems appropriate.

Diagnostic Modalities

Plain Radiography

Although plain abdominal radiography rarely adds to the evaluation of patients with blunt abdominal trauma, in cases of penetrating trauma with projectiles or retained foreign bodies it allows one to account for bullets, shrapnel, and foreign bodies. If all foreign bodies are not accounted for, one must consider the possibility that the foreign body is intraluminal or intravascular and a potential source of emboli. In patients with stab wounds or injuries without a foreign body, radiography’s utility lies in ruling out a broken instrument in the abdomen or in evaluating a large amount of free air consistent with a hollow viscous injury.

In thoracoabdominal trauma, chest radiography can identify the presence of hemothorax, pneumothorax, and possibly diaphragmatic injury. Unfortunately, its sensitivity for pneumothorax is variable, and at least two separate radiographs 4 to 6 hours apart must be taken to exclude clinically significant pneumothorax. Diaphragmatic injuries are seen clearly on plain radiographs only about 30% of the time. They cannot be excluded on the basis of normal radiographic findings.

 Ultrasonography

Focused abdominal sonography for trauma (FAST) is a useful test if positive (i.e., free fluid is found during the examination). Several authors have shown specificity and positive predictive values in the low 90th percentile for therapeutic laparotomy if ultrasound reveals free fluid. A positive ultrasound finding after penetrating abdominal trauma should lead to exploration by either laparotomy or laparoscopy. Unfortunately, although its specificity is very high, its sensitivity ranges from 21% to 70%, which is not acceptable to rule out an injury requiring laparotomy. Therefore, FAST findings negative for free fluid should be considered indeterminate, and further observation or testing is required. FAST should be able, in trained hands, to rule out significant pericardial effusion after thoracoabdominal trauma.
COMPUTED TOMOGRAPHY

The expanded use of CT is a major change in the initial evaluation of patients with penetrating trauma in the past decade. In the past, use of CT had been limited in patients with penetrating abdominal trauma because of the high incidence of bowel injury and its lack of sensitivity in diagnosing bowel and mesenteric injuries, as well as rents in the diaphragm. The newest-generation CT scanners (i.e., multidetector scanners), as well as increased familiarity with their use, have markedly improved resolution and diagnostic capabilities. It is generally agreed that CT scanning of stab wounds in stable patients without the need for immediate laparotomy is a useful approach and can obviate admission when the wound is found to be superficial. In addition, it may reveal the path of a knife, identify or rule out peritoneal violation, and show with increasing sensitivity signs of hollow viscus perforation (free intraperitoneal air, unexplained free fluid, or bowel edema). These signs remain excellent in diagnosing solid organ injury. In addition, CT may show a “contrast blush,” a sign of active bleeding or false aneurysms in patients with solid organ injuries, and may establish whether early laparotomy or angiographic intervention is warranted. Although the negative predictive value of the need for operative intervention is high, patients with peritoneal penetration and no other clear operative requirements still merit an overnight observation period. In the case of gunshot wounds the literature is a bit less clear, but it generally shows that for tangential wounds in a stable patient, CT is excellent for ruling out abdominal penetration.

Even though it has not been shown to have high enough sensitivity to rule out diaphragmatic injuries, CT has improved and may one day be useful for this role. CT is now accepted for use in stable patients with penetrating flank trauma. “Triple-contrast” (intravenous, oral, rectal) CT has been found to be highly sensitive in diagnosing injuries to retroperitoneal structures, including bowel and renal injuries. At this time, however, its sensitivity is too low to fully exclude a bowel injury, and a negative CT scan should be followed by a period of observation, usually 24 hours. The one caveat is that it should be clear on CT that the wound track is superficial and that no intraperitoneal or retroperitoneal penetration has occurred.

DIAGNOSTIC PERITONEAL LAVAGE

Though not practiced as commonly as in the past, diagnostic peritoneal lavage (DPL) is still a useful and acceptable screening tool for penetrating abdominal trauma. In unstable patients with blunt trauma, it has been supplanted by ultrasonography. With penetrating trauma, its major benefit is its high sensitivity in screening for intraabdominal penetration and injury to abdominal structures. The main drawback, in addition to a small but real number of complications, is its lack of specificity. That is, DPL tends to diagnose injuries that may be treated by observation alone. For this reason, DPL is sometimes used in patients with penetrating trauma in conjunction with less invasive (in comparison with laparotomy) procedures such as laparoscopy. It is still not entirely clear where it best fits in the overall algorithm and is probably best reserved for patients with equivocal findings on examination or concern for diaphragmatic injuries. One recent multicenter study looking at the various diagnostic options for penetrating abdominal trauma found that in stable patients, DPL did not perform markedly better than admission and serial examination. In patients with penetrating trauma who are hemodynamically unstable, it is not usually required to confirm what is already a high pretest probability that surgery is required. It may be of use, however, in patients with other possible causes of instability, especially in those with thoracoabdominal trauma, although it does not screen for retroperitoneal injuries.

A grossly bloody lavage effluent (10 mL of blood on initial aspiration) is always considered positive, although even with this finding, some surgeons will not operate immediately. If the effluent is not bloody on initial aspiration, 1 L of normal saline is instilled and then drained, and the effluent is sent to the laboratory for analysis. In patients with penetrating anterior abdominal wounds, lavage is always considered positive if the aspirate contains food particles, bile, or urine.

Cell counts tend to be a bit more controversial in that no cell count value is universally accepted to be indicative of a positive lavage result. If one is looking for penetration only, which may be useful when assessing gunshot wounds or diaphragm injuries, some institutions use as little as 1000/mm³; a more common and specific value, however, is 10,000/mm³. Although some centers use the cell count as an indication for laparotomy, others consider it complementary to observation or use CT or laparoscopy, depending on the wound. When assessing anterior abdominal wounds for injury and not just penetration, many institutions consider a cell count between 50,000/mm³ and 100,000/mm³ to be positive; a white blood cell count greater than 500/mm³ has also been used. However, these values do not seem to be particularly sensitive or specific. Alkaline phosphatase and amylase lavage effluent levels have been advocated, but it is not clear that they add much to the standard criteria.

LAPAROSCOPY

Minimally invasive laparoscopic surgery has gained general acceptance as a diagnostic and therapeutic modality in several circumstances. Although the specific injury may not always be identified, laparoscopy appears to be highly specific in identifying the need for therapeutic laparotomy. More important, in many instances it can rule out the need for laparotomy completely with a high degree of sensitivity. Its most accepted use is for low-velocity wounds when diaphragmatic injury (i.e., wounds involving the left thoracoabdominal area) is a possibility. It is also a reasonable tool to use in stable patients with anterior abdominal wounds to screen for peritoneal penetration and the need for laparotomy. The overall benefit, however, in this group of patient, over less invasive approaches such as serial examination, has not been well proven. It may be used in the operating room as an initial intervention in a stable patient with penetrating abdominal trauma and equivocal findings on physical examination. It allows a survey of the abdominal contents, repair of minor injuries, and possible avoidance of laparotomy with its associated complications. Its major drawbacks are its relative invasiveness, need for general anesthesia, and cost, as well as some literature showing suboptimal sensitivity for hollow viscus injury.

DIAGNOSTIC TESTING FOR SPECIFIC INJURIES

Anterior Stab Wounds

In patients with anterior stab wounds, the first step is to decide whether peritoneal penetration has occurred. This may be accomplished by local wound exploration, DPL, or CT. If
lavage or local exploration is clearly negative, no further management other than local wound care is indicated. If lavage or CT shows peritoneal penetration but no indication for emergency surgery, options include laparoscopy, laparotomy, and serial observation. Depending on the center, all may be appropriate, although laparoscopy or serial observation provides the best risk-benefit balance. For observation to be successful, patients must be able to cooperate with serial examinations and have evidence of continued hemodynamic stability, and peritonitis should not develop. Prolonged observation is rarely possible in the ED, and these patients are generally admitted to a surgical service where serial examinations are possible.

**Flank Wounds**

Flank wounds require triple-contrast CT scanning. If the results are negative, a period of observation is standard. In patients with a left-sided thoracoabdominal wound, a negative ED work-up is often followed by laparoscopy to exclude an occult diaphragmatic injury. Patients who have stab wounds in the flank or back and are stable without obvious signs of bowel injury (peritonitis, hypotension) should undergo triple-contrast CT scanning of the abdomen and pelvis. If the results are negative, such patients should be admitted for 24-hour observation, as previously described.

**Gunshot Wounds**

It is common and acceptable to explore all gunshot wounds that penetrate the peritoneum. If it is unclear whether penetration has taken place, a plain film radiograph may show an intraperitoneal bullet. Alternatively, DPL with appropriate cell counts is sensitive for intraperitoneal penetration. A positive FAST finding with free fluid in the abdomen should prompt operative exploration. Although serial physical examinations have been advocated, this is usually performed in conjunction with an intravenous or oral contrast-enhanced (or both) CT scan of the abdomen and pelvis. CT has been shown to be effective in stable patients with tangential gunshot wounds to rule out intraperitoneal penetration. If it is clear that penetration of the peritoneum did not occur, the patient may be discharged. If penetration occurred, the patient may remain under observation or may undergo laparotomy or possibly laparoscopy or angiography, depending on the injury complex.

**Other Injuries**

**ISOLATED BOWEL INJURIES**

Patients with bowel injury alone or injury to the liver or spleen without significant bleeding may have minimal symptoms initially. Given that hollow viscus injury is much more common with penetrating trauma than with blunt trauma, the EP must search for these sometimes subtle or delayed findings. Tenderness at the wound site is normal, but peritoneal findings such as diffuse tenderness and muscular rigidity, regardless of stability, are generally indicative of the need for operative intervention.

These findings may become apparent several hours into a patient’s course if the injury involves rupture of a hollow viscus. Over time, intraperitoneal inflammation increases, stimulates somatic pain fibers, and becomes evident clinically.

**DIAPHRAGMATIC INJURIES**

Diaphragmatic injuries may have dramatic findings but can also be occult and be accompanied by symptoms or even fatal complications years after the initial injury. Any patient with a thoracoabdominal injury may have a diaphragmatic injury. The rate of diaphragmatic injury varies from 7% to 42% in patients with penetrating thoracoabdominal trauma. The diagnostic rate varies with the aggressiveness of evaluation; if it is not looked for, many diaphragmatic injuries will be missed. It tends to be highest in patients with left costal penetration. Most left-sided tears can be repaired surgically. A small right-sided tear may not need to be repaired because herniation is much less likely on this side as a result of protection by the liver. In cases of potential left diaphragmatic injury, laparoscopy or DPL is a reasonable addition to the diagnostic approach.

**TREATMENT**

Most interventions and procedures in patients with penetrating trauma (Table 80.1) are aimed at first determining whether intraabdominal penetration occurred and, if so, deciding

</table>
whether the patient can avoid a nontherapeutic laparotomy. The options are varied and may be performed alone or in series depending on the test, findings, and local custom. Although mandatory exploration was once the paradigm for penetrating injuries, knowledge of significant morbidity from negative laparotomy has pushed surgeons toward a much more conservative approach to management.\textsuperscript{22,30,31}

Exploration requires aseptic technique, good overhead lighting, and local lidocaine and epinephrine anesthesia. Inserting a digit or cotton swab into the wound is not an acceptable alternative. Obese or noncooperative patients and those with abdominal scarring from previous operations are not optimal candidates. Paralleling the natural skin lines, the wound is enlarged as necessary so that the posterior fascia may be evaluated. If penetration of the anterior fascia has occurred or if the wound exploration is inconclusive, the wound is considered intraperitoneal and must be evaluated further by more invasive methods or by observation and serial examinations. A recent multicenter observational study suggested that serial examinations are a safe option. Operative evaluation based solely on penetration would lead to a high number of nontherapeutic laparotomies (57\%).\textsuperscript{17} If the fascia is clearly intact, the wound can be irrigated and closed by primary intention if clean and the patient discharged. Alternatively, the initial wound can be closed by secondary intention or delayed primary closure.\textsuperscript{23}

**FLUID RESUSCITATION**

Resuscitation of hypotensive patients remains a widely discussed and controversial area of treatment. The advanced trauma life support standard treatment is to administer 2 L of intravenous fluid followed by transfusion of blood; however, some EPs and surgeons prefer to limit resuscitation until definitive control is obtained\textsuperscript{32,33} because of concerns that elevation in blood pressure through aggressive administration of fluids may disrupt clots and clotting factors, as well as evidence in multiple animal studies that less aggressive resuscitation or “permissive hypotension” leads to improved outcomes.

Two well-done large prospective trials have been carried out in humans, a study of penetrating torso injuries by Bickell et al. and a study of a combination of blunt and penetrating injuries by Dutton et al.\textsuperscript{32,34} The Bickell trial enrolled 598 patients with penetrating trauma and a systolic blood pressure of 90 mm Hg or lower. The authors found a trend toward lower mortality and morbidity in the minimally resuscitated patients, although the “appropriately resuscitated” patients—or those with standard high fluid volume—had blood pressure values that were significantly higher after resuscitation but before surgery. The Dutton study\textsuperscript{32} of approximately 100 patients compared the outcomes of actively bleeding patients treated via the standard resuscitation protocol with the outcomes of patients treated with a “hypotensive resuscitation” protocol consisting of a target systolic blood pressure of 70 mm Hg. Neither the standard group nor the hypotensive group showed improvements in mortality or worse outcomes; however, there was difficulty reaching the target blood pressures. In the authors’ judgment, limiting resuscitation with normal saline and blood to reach a target systolic blood pressure of around 90 mm Hg appears to be reasonable. Moving more rapidly to blood replacement rather than excessive saline is probably a reasonable approach also. In patients with massive blood loss, the current literature suggests blood replacement protocols with increased use of platelets and clotting factors, although the exact ratios remain unclear and somewhat controversial.\textsuperscript{35,36} It may not be feasible, appropriate, or beneficial to allow the blood pressure to decrease much lower.

**PRIORITY ACTIONS**

| Immediate attention to the ABCs (airway, breathing, and circulation) |
| Immediate transport to the operating room for diffuse peritonitis or hemodynamic stability |
| Evaluation of stable patients with local wound exploration when possible to exclude peritoneal penetration |
| Admission if penetration has occurred or evaluation is unclear |
| Antibiotics if surgery is planned |
| Documentation of the location and appearance of all wounds |
| Consultation with a trauma practitioner or general surgeon |
| Exclusion of pulmonary, diaphragm, or cardiac injury |

**ANTIBIOTICS**

Despite the dearth of high-quality prospective research to support the practice, most expert opinion and guidelines recommend that antibiotics be administered to any patient with a penetrating injury who will undergo operative intervention. The antibiotics are generally continued for 24 hours postoperatively. Perioperative antimicrobial coverage directed against skin and enteric flora will decrease postoperative wound infections. A single agent with broad-spectrum aerobic and anaerobic coverage is recommended. Alternatively, combination therapy with clindamycin or cefazolin and an aminoglycoside is appropriate. Patients allergic to cephalosporin or penicillin may receive vancomycin instead for gram-positive coverage.\textsuperscript{27}

No clear guidelines have been established for patients with wounds that have not penetrated the peritoneum and who will not undergo surgery. Essential to decreasing wound infection is high-pressure irrigation. It may be reasonable to offer a 5-day course of prophylactic antibiotics to patients who have significant devitalized tissue or irretrievable foreign bodies. It is more judicious to allow closure of these wounds by secondary or delayed primary intention.

**TETANUS PROPHYLAXIS**

Because of the rarity of the disease and successful public health measures, clinical tetanus is exceedingly rare in the United States. Only one case of a traumatic gunshot wound was reported to cause tetanus in the United States between 1998 and 2000. Penetrating trauma may carry *Clostridium tetani* into the wound, but most patients born in the United States are properly immunized. A prospective observational case series in 2004 found a 90.2% seroprevalence of tetanus immunity in 1988 patients with acute wounds seen in five U.S. urban EDs. Elderly patients and those from outside North America or western Europe are at higher risk. Mexican Americans between 20 and 44 years of age who were born outside the United States appear to be at higher risk. Most cases worldwide are due to neonatal tetanus.\textsuperscript{38}
If they have not received a tetanus shot within the previous 10 years, patients with stab or gunshot wounds should be treated with tetanus toxoid. All patients not previously fully immunized or with unclear status should be given both tetanus toxoid and tetanus immunoglobulin. It is not always necessary to give the booster in the ED because it may be administered up to several days after the injury. However, it is often preferable because tetanus immunization may not be part of the usual care in the hospital or outpatient setting.

PAIN CONTROL

Although pain control is generally thought to be appropriate and safe in patients with nontraumatic abdominal pain, little scientific literature is available to guide the treatment of patients with traumatic injury when observation is planned.

It seems clear that in a patient who will require operative intervention, withholding pain control offers no diagnostic benefit. Care should be taken, however, before giving large doses of pain medication that may decrease the blood pressure or when treating patients with preexisting shock. Fentanyl, titrated appropriately, may be a better choice than morphine or when treating patients with preexisting shock. Care should be taken, however, before giving large doses of pain medication that may decrease the blood pressure or when treating patients with preexisting shock. Fentanyl, titrated appropriately, may be a better choice than morphine.

Among patients with nontraumatic abdominal pain, little scientific literature is available to guide the treatment of patients with traumatic injury when observation is planned.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Final disposition is usually based on the location of the injury, the implement used, the patient’s hemodynamic status, and the EP’s and surgeon’s preferred evaluation methods. As discussed previously, several different approaches can be taken, from conservative observation to aggressive operative approaches. As is true with all trauma, the ABCs (airway, breathing, and circulation) are the first line in management. In general, patients with evidence of signs of shock or diffuse peritoneal findings should be taken to the operating room. The one final caveat is that patients who may have concomitant cardiac or pulmonary injuries should have them ruled out as a source of the hypotension.

TIPS AND TRICKS

Always undress the patient fully and examine the back, axilla, and groin areas for occult penetrating trauma.

Always account for all bullets in cases of penetrating trauma (e.g., if only one wound is present, the bullet should still be inside the body).

In general, the number of bullets and the number of entrance and exit wounds should add up to an even number. For example, a single wound would suggest that a bullet is still in the body (1 bullet + 1 wound = 2). Three wounds suggest either one or three bullets in the body (2 entrance wounds + 1 exit wound + 1 bullet = 4; 3 entrance wounds + 3 bullets = 6).

Ultrasonography can always be used to rapidly distinguish hypovolemic shock from distributive shock by looking for collapse of the inferior vena cava with inspiration. Penetrating trauma is a reportable injury in most of the United States. Make sure that your emergency department is in compliance with local laws.

A single chest radiograph cannot exclude pneumothorax with a thoracoabdominal wound.

Negative results on ultrasonography have little predictive value with penetrating abdominal trauma; however, positive findings on ultrasonography have high predictive value for therapeutic laparotomy.

Pelvic Fractures

Leigh A. Patterson

**KEY POINTS**

- Approximately 70% of patients with a traumatically disrupted pelvic ring will have a major associated injury.
- If a patient has displacement of 0.5 cm at any fracture site in the pelvis or has an “open book” pelvic fracture, massive transfusion may be needed.
- Blood loss from open book pelvic fractures and vertical shear injuries can be life-threatening.
- Emergency binding of the pelvis can help reduce pelvic volume and tamponade the bleeding. Binding the fractured pelvis too tightly should be avoided.
- Interventional radiology can embolize the vessels.

**EPIDEMIOLOGY**

Fractures of the bony pelvis account for 3% of all fractures; however, the overall mortality from pelvic ring injuries is 10% to 15%. Motor vehicle collisions (MVCs) involving cars or cars and pedestrians cause approximately 60% of pelvic fractures. Side-impact car collisions more commonly cause pelvic fractures than do head-on car collisions. Falls and motorcycle accidents are also significant causes of pelvic ring injuries.

The blood supply and innervation of the pelvic organs and lower extremities are intimately linked to the pelvic architecture. Major disruptions lead to life-threatening blood loss, damage to urogenital organs, and neurologic deficits. The emergency physician (EP) must identify patients at risk for pelvic ring disruption and aggressively work to control bleeding.

**PATHOPHYSIOLOGY**

The pelvis provides support for upright mobility by connecting the spine to the lower extremities. When viewed as a whole, the pelvis contains a major ring and two inferior rings. The triangular sacrum and two innominate bones form the major pelvic ring (Fig. 81.1). The sacrum is a fusion of the five sacral vertebrae and distributes the weight of the upper part of the body to the innominate bones. The sacrum also conducts the sacral nerve roots to the pelvic organs. Each innominate bone is a fusion of the ilium, ischium, and pubic bones. The intersection of the fusion forms the acetabulum, which articulates with the femur. Posteriorly, the innominate bones are anchored to the sacrum by the anterior and posterior iliac ligaments, two of the body’s strongest ligaments. The sacrotuberous and sacrospinous ligaments attach the sacrum to the ischial tuberosity and the ischial spines bilaterally, thus further reinforcing the posterior arch of the pelvic ring.

Anteriorly, the innominate bones are anchored to each other at the cartilaginous pubic symphysis. Because the innominate and sacrum are dense bone anchored together with equally dense connective tissue, disruption of the architecture of the major pelvic ring requires tremendous force and usually results in bony fractures or ligamentous disruptions at two or more sites in the ring. The inferior rings are formed by the pubic and ischial rami. They serve as attachments for muscles of the thighs and do not bear weight from the upper part of the body. Low-force mechanisms such as straddle injuries and falls onto the buttocks can fracture the rings, usually an isolated pubic ramus.

The left and right internal iliac arteries course in the region of the sacroiliac joints; they branch and form a network of vessels in the posterior pelvic arch. Posteriorly, the superior gluteal artery is commonly injured. Throughout the pelvis, arteries and veins are easily injured during the impact that causes the pelvic fracture, and blood collects in the retroperitoneal space.

*Laterally compression*, caused by injuries involving the side, crushes the pelvis inward; therefore, massive pelvic bleeding is uncommon with these types of injury. Sacral crush fractures and horizontal pubic ramus fractures can be diagnosed radiographically. Sacroiliac diastasis may also occur.

*Anteroposterior compression* forces cause the iliac wings to rotate outward, as when a pedestrian is struck directly anteriorly or posteriorly by a car. The fractures are unstable and pelvic volume increases, which allows massive retroperitoneal venous or arterial pelvic bleeding to occur. Diastasis of the anterior pelvic ring may be evident and is often termed an open book pelvic fracture. The posterior ligaments (as a guiding principle) can withstand about 2.5 cm of symphyseal diastasis before the sacral ligaments are disrupted. Associated acetabular fractures are commonly present in about half of cases.

*See “Tile Classification of Pelvic Fractures” in text for discussion of types of fractures.

**Vertical shear** injuries are less common and result from axial force through the legs or spine to the pelvis. The anterior and posterior rings are both disrupted. As the hemipelvis is forcibly sheared, pelvic volume increases, which results in massive bleeding.

Several classification schemes involving the direction of force applied to the pelvis, the bones injured, the degree of instability of the ring, and any associated injuries are used for pelvic ring disruptions. Fracture stability and increases in pelvic volume determine the magnitude of blood loss and potential mortality. See Box 81.1.

**Tile Classification of Pelvic Fractures**

The Tile classification adopted by the Orthopedic Trauma Association describes pelvic fractures by the degree of stability. The type and degree of stability predict outcome and associated injuries (see Box 81.1). Type A fractures are stable and include avulsion fractures and isolated fractures of an inferior pubic ramus, iliac wing, or distal sacrum. These fractures cause local pain but do involve the major pelvic ring.

Type B and C fractures are unstable fractures resulting from high-energy force. In both types the pelvic ring is disrupted in two or more places. These disruptions can consist of any combination of fractures and ligament tears. Disruptions may be unilateral, with involvement of only one hemipelvis, or bilateral, with one or more disruptions in both hemipelvises.

Type B fractures are vertically stable but rotationally unstable. These ring disruptions usually involve anterior structures, the superior pubic rami and pubic symphysis and the anterior iliac ligaments. The sacrum and the posterior iliac ligaments are spared. Lateral trauma from a side-impact MVC or anteroposterior trauma from a frontal-impact MVC can cause fractures in this class. The axis of a bony fracture is determined by the orientation of the force applied to the pelvis.

Type C fractures are both vertically and rotationally unstable because the posterior elements of the major pelvic ring are disrupted by a fracture through the sacroiliac joint, which is a complete tear. In addition to lateral and anteroposterior forces, vertical shear mechanisms, including falls, can cause type C fractures.

Avulsion fractures of the pelvis at muscle insertion sites are caused by forced contraction of the thigh muscles when moving the hip. The apophyses at the anterior superior iliac spine, the anterior inferior iliac spine, and the ischial tuberosity fuse between the ages of 16 and 25. Adolescent athletes involved in strenuous sports are vulnerable to these injuries. EPs should suspect these injuries based on the mechanism of injury (Table 81.1).

**Presenting Signs and Symptoms**

The classic findings in patients with a major pelvic ring disruption include a chief complaint of pelvic pain or pain with movement at the hips. However, nearly 70% of patients with disruption of the major pelvic ring have associated injuries, such as closed head trauma, blunt chest and abdominal trauma, and long-bone fractures, that may mask the symptoms of pelvic pain.

The EP should first suspect a pelvic fracture based on the mechanism of injury and then search for additional signs of

**TREATMENT**

Pelvic fractures need to be reduced rapidly and fixated to prevent ongoing blood loss and promote healing. Reduction of a major pelvic ring disruption should increase interstitial pressure in the pelvis and at the bony surfaces of a fracture to tamponade any venous bleeding. Pelvic volume is also directly related to diastasis at the sites of ligamentous disruption, namely, the pubic symphysis and sacroiliac joints. A 1-cm widening of the pubic symphysis allows pelvic volume to expand 4.6%. A combined 8-cm widening of the pubic symphysis and sacroiliac joints would allow potentially 500 mL of blood to accumulate in the pelvis before the soft tissues even begin to tamponade the bleeding.

Prehospital providers should obtain large-bore intravenous access and immobilize the patient on a long spine board.

Initially, the EP can reduce the fracture by applying a sheet circumferentially around the pelvis and tying it so that pelvic volume is reduced (Figs. 81.3 to 81.5). Commercial binders can be applied in the same manner. Such reduction works best for fractures with external rotation of one or both hemipelves, such as an open book pelvic fracture. The EP should be careful to not overcorrect the external rotation by binding the pelvis too tightly. Overcorrection could force sharp bony fragments into the pelvic vasculature and organs.

Orthopedic surgery should be consulted early for reduction of pelvic ring disruptions. Circumferential binding is a temporary reduction and will not stabilize a vertically unstable fracture. Patients with ongoing blood loss may need external fixators to stabilize the ring.

Bleeding can be life-threatening, and the posterior pelvic venous plexus accounts for more than 80% of hemorrhages.

Early transfusion is indicated, particularly for patients with vertical shear or anteroposterior compression fractures. If a patient has 0.5-cm displacement at any fracture site in the pelvis or an open book pelvic fracture, massive transfusion will probably be needed. Patients who are persistently...
Mortality in patients with hemorrhagic shock from a pelvic fracture is about 50%. Patients who undergo repair of major pelvic ring injuries may have chronic pelvic pain and typical operative complications, including infection and bleeding. Concomitant head, chest, and abdominal injuries will contribute to the overall complication rate of pelvic fractures.

Patients with unstable pelvic fractures will need to be admitted to a surgical intensive care unit for close hemodynamic and neurologic monitoring. Because many of these patients will have additional head, chest, abdomen, and limb injuries, they are best managed primarily by a trauma surgeon in consultation with orthopedists, vascular surgeons, urologists, and interventional radiologists. If multidisciplinary trauma services are not available at the initial facility, the EP must stabilize the patient and arrange emergency critical care transport for these patients to a designated trauma center.

Patients with single ring disruptions who are able to bear weight and ambulate with minimal assistance may be discharged home with pain control and referral to physical therapy. If they are unable to bear weight, they may need admission to a primary care service for physical and occupational therapy consultation.

Follow-up should also be scheduled with a sports medicine specialist or orthopedic surgeon who will monitor healing and guide the patient’s return to athletic activity.

**RED FLAGS**

- Mortality in patients with hemorrhagic shock from a pelvic fracture is about 50%.
- Patients who undergo repair of major pelvic ring injuries may have chronic pelvic pain and typical operative complications, including infection and bleeding.
- Concomitant head, chest, and abdominal injuries will contribute to the overall complication rate of pelvic fractures.

**TIPS AND TRICKS**

**Pelvic Binder Application**

To reduce the volume of an open book pelvic fracture, a bedsheets can be used in place of a commercial binder (see Fig. 81.4).

Fold the sheet lengthwise into thirds. Logroll the patient to place the sheet or binder posterior to the pelvis. The superior edge of the sheet should be just inferior to both iliac crests. The umbilicus or natural waist should not be covered by the sheet. The inferior edge should not extend below the lesser trochanter. The sheet should be knotted anterior to the patient with enough torque to reduce the symphysis diastasis to nearly normal: 1 to 3 cm for many patients.

Genitourinary Trauma
Michael S. Runyon and Michael A. Gibbs

KEY POINTS

- Evaluate suspected genitourinary tract injuries in retrograde fashion; check for urethral disruption before bladder rupture and bladder rupture before ureteral or kidney injury.
- Suspect urethral injury in blunt trauma patients with a significant pelvic fracture, blood at the urethral meatus, gross hematuria, absent or abnormally positioned prostate on digital rectal examination, and ecchymosis or hematoma involving the penis, scrotum, or perineum.
- Evaluate urethral integrity by retrograde urethrography when urethral injury is suspected and a urinary catheter cannot easily be placed with a single gentle attempt.
- Suspect bladder rupture in blunt trauma patients with pelvic trauma and gross hematuria and in those sustaining a significant pelvic fracture.
- Suspect upper tract (kidney or ureter) injury in blunt trauma patients with gross hematuria or with microscopic hematuria when the patient has sustained a significant decelerating mechanism or exhibits hypotension.
- Suspect genitourinary involvement when any penetrating injury is inflicted in proximity to the genitourinary system.

EPIDEMIOLOGY

 Approximately 10% of trauma patients sustain injury to the genitourinary system. The majority of these injuries (approximately 80%) are the result of a blunt trauma mechanism. Timely identification and management of genitourinary injuries can minimize the associated morbidity, which may include impairment of urinary continence and sexual function. Identification of injury depends on a stepwise evaluation with consideration of the mechanism of injury, pertinent findings on physical examination, urinalysis, and appropriate diagnostic imaging performed in the correct sequence.

PATHOPHYSIOLOGY

Anatomically, the genitourinary system is divided into lower and upper tracts. This division is clinically important because specific mechanisms tend to injure different parts of the genitourinary system. The lower genitourinary tract consists of the external genitalia, urethra, and bladder (Figs. 82.1 and 82.2). The upper genitourinary tract consists of the ureters and kidneys.

EXTERNAL GENITALIA

The male external genitalia consist of the penis, scrotum, testicles, and ejaculatory complex. The female external genitalia consist of the vagina and vulva; the latter includes the labia majora, labia minora, and clitoris.

Injuries to the external genitalia may occur by blunt or penetrating mechanisms or by circulatory compromise induced by constricting devices applied either accidentally (as in the case of a hair tourniquet) or intentionally (e.g., to enhance sexual performance and pleasure). Additionally, the skin of the penis, scrotum, or labia may become ensnared by a metal zipper. Blunt trauma mechanisms include a kick or other direct blow to the genitals, falls, and straddle injuries. Penile fracture is a blunt injury that occurs when an erect penis is bent suddenly and forcefully, with rupture of the tunica albuginea of one or both of the corpora cavernosa. This injury occurs most commonly during sexual intercourse when the penis slips out of the vagina and strikes the partner’s pubis or perineum, but it may also occur during masturbation. Significant injury to the external genitalia may accompany pelvic fractures. Penetrating injuries may be inflicted by gunshot wounds, knives, or other sharp objects.

URETHRA

The male urethra is divided into anterior (bulbous and pendulous) and posterior (prostatic and membranous) portions. Traditionally, this division has been described at the level of the urogenital diaphragm; however, recent work has questioned the existence of this structure, as classically taught. Regardless, the weakest point of the posterior urethra is the bulbomembranous junction, and it is the area where the majority of posterior urethral disruptions occur.

Injuries to the anterior urethra occur from direct blows, straddle injuries, or instrumentation or in conjunction with a penile fracture (Fig. 82.3). By contrast, posterior urethral injuries usually occur in the setting of significant pelvic fractures, often caused by motor vehicle collisions (Fig. 82.4). Penetrating injuries may be inflicted by gunshot wounds, knives, or other sharp objects. Urethral injuries are much less common in women because the female urethra is short and relatively mobile and lacks significant attachment to the pubis.
Posterior urethral disruption occurs when a significant pelvic fracture causes upward displacement of the bladder and prostate. Avulsion of the puboprostatic ligament is followed by stretching of the membranous urethra and subsequent partial or complete disruption at the anatomic weak point, the bulbomembranous junction.

Overall, urethral disruption accompanies pelvic fracture in approximately 5% of cases in women and up to 25% of cases in men. However, the risk for urethral injury varies with the type of pelvic fracture. High-risk fractures include concomitant fractures of all four pubic rami (straddle fractures; Fig. 82.5) or fractures of both ipsilateral rami accompanied by massive posterior disruption through the sacrum, sacroiliac joint, or ilium. Low-risk injuries include single ramus fractures and ipsilateral ramus fractures without disruption of the posterior ring. The risk for urethral injury approaches zero with isolated fractures of the acetabulum, ilium, and sacrum.

Posterior urethral disruption occurs when a significant pelvic fracture causes upward displacement of the bladder and prostate. Avulsion of the puboprostatic ligament is followed by stretching of the membranous urethra and subsequent partial or complete disruption at the anatomic weak point, the bulbomembranous junction.

**BLADDER**

When empty, the bladder lies along the floor of the pelvis, where it is relatively protected unless the force of an injury fractures the bony pelvis. When distended by urine, the
a pelvic fracture, and the injuring force causes rupture at the anterior or anterolateral wall. In other cases, bony fragments from the pelvic fracture impale the bladder and result in extra-peritoneal rupture. Penetrating injuries may be inflicted by gunshot wounds, knives, or other sharp objects.

URETERS
The ureters course distally along the psoas muscles and enter the bladder posteriorly and inferiorly at the trigone. Ureteral injury is rare and occurs in less than 1% of all genitourinary injuries. Ureteral injury is rare and occurs in less than 1% of all genitourinary injuries. In adults, penetrating injuries account for approximately 90% of cases, most commonly inflicted by gunshot wounds. In children, the most common mechanism is blunt avulsion at the ureteropelvic junction as a result of a motor vehicle collision or a fall from a height. This injury pattern is thought to be due to the increased mobility of the pediatric vertebral column, which allows extreme hyperextension that results in upward displacement of the kidney and separates it from the relatively immobile ureter.

KIDNEYS
The kidneys lie in the retroperitoneal space and are protected by the lower ribs, the back musculature, and perinephric fat. The right kidney extends lower than the left one because of the presence of the liver. Significant force is required to injure the kidney. Motor vehicle collisions, falls, direct blows, and lower rib fractures are common mechanisms. Significant decelerating force may cause avulsion of the renal pedicle. In children, bicycle accidents represent a prominent mechanism of renal injury. Penetrating injuries may be inflicted by gunshot wounds, knives, or other sharp objects.

PRESENTING SIGNS AND SYMPTOMS
EXTERNAL GENITALIA INJURIES
Blunt scrotal trauma may result in superficial ecchymosis and swelling or testicular rupture, torsion, or displacement. In testicular rupture, the tunica albuginea is disrupted. Even in the absence of testicular rupture, blood or fluid may

---

**Fig. 82.3** Anterior urethral injury. Note the extravasation of blood at the injury site (arrow) with dissection into tissues of the scrotum and perineum.

**Fig. 82.4** Posterior urethral injury. Note the displacement of the prostate by the hematoma at the site of injury (arrow).

**Fig. 82.5** Straddle pelvic fracture. Note the concomitant fractures of all four pubic rami. This injury confers a high risk for urethral disruption.
accumulate between the tunica albuginea and tunica vaginalis and result in a hematocoele or hydrocele, respectively. Testicular torsion disrupts the vascular supply and causes ischemia. Testicular displacement occurs when the testicle is forced from the scrotum, usually into the peritoneal cavity. Physical examination may be limited because of pain and swelling.

Penile fracture is often accompanied by an audible snapping sound and is followed immediately by severe pain, detumescence, swelling, and ecchymosis. The corpus spongiosum is involved in 20% to 30% of cases, and urethral injury occurs in 10% to 20%. If the Buck fascia remains intact, the swelling and ecchymosis are confined to the penile shaft. If not, blood and urine may dissect into the scrotum, perineum, and suprapubic spaces.8,9

In patients with penetrating mechanisms, a careful and complete physical examination should be conducted to search for associated or additional occult injuries. In one series, gunshot wounds involving the penis were associated with injury to other organ structures in 80% of cases.10 Violation of the corpora cavernosa requires operative intervention and is heralded by an expanding penile hematoma, significant bleeding from a wound to the penile shaft, or a palpable corporal defect.

Injuries to the female genitalia are often associated with pelvic fractures. Important mechanisms include physical or sexual assault, consensual intercourse, and penetrating injuries. In the presence of a pelvic fracture or blood at the introitus, meticulous vaginal examination is mandated. Complications of missed vaginal injuries include infection, fistula formation, and significant hemorrhage.11,12 In one series, 25% of women sustaining injury to the external genitalia required red blood cell transfusion because of blood loss from the genital injury alone.11

URETHRAL INJURIES
In blunt trauma, the signs and symptoms of urethral injury include blood at the urethral meatus, gross hematuria, inability to void, absent or abnormally positioned prostate on digital rectal examination, or ecchymosis or hematoma involving the penis, scrotum, or perineum. In penetrating trauma, urethral disruption should be suspected when the injury trajectory lies in proximity to the urethra.

BLADDER INJURIES
The vast majority of blunt bladder injuries are accompanied by gross hematuria, significant pelvic fracture, or both. In general, the diagnosis may be excluded clinically when both are absent. Bladder injury may occur with any pelvic fracture but is more likely with fractures of the anterior arch or when all four pubic rami are fractured. A minority of patients will have a pelvic fracture with microscopic hematuria. Additional signs and symptoms include lower abdominal pain or tenderness and inability to void. In patients with penetrating trauma, bladder rupture should be evaluated when the injury trajectory lies in proximity to the bladder.

URETERAL INJURIES
Hematuria (gross or microscopic) is not a reliable predictor of ureteral injury because the findings on urinalysis are normal approximately 25% of the time.7,12 The diagnosis is frequently missed on the initial evaluation because the signs and symptoms are minimal and nonspecific. Delayed findings include fever, flank pain, and a palpable flank mass (urinoma). Ureteral injury should be considered in patients with any penetrating injury that has a trajectory in proximity to the ureter.

KIDNEY INJURIES
Clinical clues to a potential renal injury include bruising, pain, or tenderness in the flank or abdomen; rib or spine fractures; and hematuria, injury to other organs, and shock. In patients with penetrating trauma, renal involvement should be suspected when the injury trajectory is in proximity to the kidney.

DIGITAL RECTAL EXAMINATION
Classic teaching has held that digital rectal examination provides useful clinical information in the evaluation of a blunt trauma patient who has sustained a pelvic fracture or in whom a urethral injury is suspected. The technique described includes evaluation for an absent or high-riding prostate, the presence of which may be associated with posterior urethral disruption and the need for prompt investigation for urethral integrity. However, multiple studies have now demonstrated a relative lack of utility of digital rectal examination for the detection of urethral injuries.14-16 Accordingly, the decision to evaluate for urethral injury should not rely solely on the findings of digital rectal examination but instead should consider additional clinical features, including the mechanism of injury, physical examination findings such as a scrotal or perineal hematoma or blood at the urethral meatus, and the presence and type of any associated pelvic fracture.

VAGINAL EXAMINATION
Although most multiply injured patients receive a digital rectal examination, the vaginal examination is often omitted in error. To avoid missing occult injuries that may result in significant and potentially life-threatening hemorrhage and infection, a careful vaginal examination should be performed to identify any lacerations or bone fragments in all women with pelvic fractures. This is especially critical in patients with fractures of the anterior pelvic ring.

HEMATURIA
Hematuria is a marker of potential injury to the genitourinary tract. It is important to inspect the initial urine output to avoid missing transient hematuria that may clear with ongoing fluid resuscitation. A spontaneously voided specimen is ideal but is frequently impractical in a multiply injured patient.

Gross hematuria is defined as urine that is any color other than clear or yellow. This is a necessarily conservative definition because the degree of gross hematuria does not correlate with the severity of the injury; a relatively minor urethral injury may result in impressive hemorrhage, whereas major vascular disruption may be accompanied by only slightly discolored urine. False-positive results may be due to many factors, including ingestion of certain food products or dyes, various medications, or the presence of free myoglobin because of rhabdomyolysis.

Microscopic hematuria is defined as more than five red blood cells per high-power field (RBCs/HPF) or a positive dipstick evaluation. The significance of gross versus microscopic hematuria varies with the mechanism of injury (blunt versus penetrating) and is discussed in more detail later in the chapter.
Retrograde urethrogram showing complete urethral embolization.19

Diagnosis of injuries to the external genitalia is based largely on the mechanism of injury and physical examination. Unexplained penile or clitoral swelling necessitates a careful search for a hair tourniquet, especially in infants and young children. Concomitant urethral injury should be considered and a retrograde urethrography performed to assess urethral integrity in any patient with a penile fracture, blood at the urethral meatus, or penetrating trauma that violates the Buck fascia. Plain radiographs revealing a significant pelvic fracture should prompt a careful examination for occult rectal or vaginal injury.

Ultrasonography is used to evaluate testicular blood flow in cases of suspected torsion and to supplement the physical examination in cases of testicular trauma. However, this modality has only modest sensitivity and specificity in detecting testicular rupture and is quite operator dependent.9,17

After the initial history and physical examination, an anteroposterior (AP) pelvic radiograph should be obtained to assess for fracture. In cases of suspected urethral injury, classic teaching has held that it is imperative to evaluate the integrity of the urethra with a retrograde urethrogram before attempting to place a urinary catheter to avoid worsening a partial urethral disruption. Although the literature on this topic is sparse, one small retrospective review of 13 cases of urethral injury demonstrated no evidence that a blind attempt to insert a urinary catheter worsened the initial injury.18 Consequently, in the presence of gross hematuria without other signs of urethral injury, it is reasonable to make one attempt at passing a Foley catheter. If resistance is encountered, the attempt should be aborted and urethral integrity evaluated by retrograde urethrography. This procedure should be deferred if pelvic angiography is indicated because extravasation of contrast material from a urethral injury may obscure computed tomography (CT) and angiography images and complicate attempts to control significant pelvic hemorrhage by vascular embolization.19

**Retrograde Urethrography Procedure**

The patient should be kept supine to avoid potentially disrupting a stable pelvic hematoma. Obtain a baseline kidneys, ureter, and bladder (KUB) radiograph and ensure that the film captures the entire course of the urethra and bladder. Retract the foreskin, if present, and control the shaft of the penis with a 4 x 4-inch gauze pad to prevent slippage. Stretch the penis obliquely over the thigh to promote unfolding and visualization of the entire urethra. Fill a 60-mL syringe with 10% water-soluble contrast material (diluted in sterile saline) and attach a Christmas tree adaptor. Insert the adaptor snugly into the urethral meatus and ensure a tight fit because leaking contrast material will result in spurious findings.

Alternatively, a Foley catheter can be inserted a few centimeters into the urethra and the balloon inflated to ensure a snug fit within the fossa navicularis; next, attach a catheter-tip syringe filled with contrast material as described previously. Inject 50 to 60 mL (0.6 mL/kg in children) of contrast agent and obtain a KUB radiograph simultaneously with infusion of the final 10 mL. Lack of urethral extravasation with filling of the bladder indicates a normal study. Partial disruption is indicated by urethral extravasation accompanied by partial filling of the bladder. Complete disruption results in urethral extravasation with no filling of the bladder (Fig. 82.6).

If urethral injury is suspected, obtain a retrograde urethrograph first to ensure urethral integrity before placement of a Foley catheter. Once urethral injury is excluded and a Foley catheter has been placed, evaluate for bladder rupture in all patients with gross hematuria and in those who have sustained a significant pelvic fracture. This is accomplished by retrograde cystography or retrograde CT cystography. Additional relative indications for bladder imaging include gross hematuria without pelvic fracture and microscopic hematuria with pelvic fracture.50

**Retrograde Cystography Procedure**

As with the procedure for retrograde urethrography, the patient should be kept supine to avoid potentially disrupting a stable pelvic hematoma and care taken to avoid spillage of the contrast agent, which will result in a spurious study. Obtain a baseline KUB radiograph. Remove the central piston from a 60-mL catheter-tip syringe and attach it to the Foley catheter. Hold the syringe upright above the level of the bladder and instill 400 mL of 10% water-soluble contrast agent (diluted in sterile saline) by gravity. In patients younger
to pass, refill the bladder to the point of contraction, and then forcefully inject another 50 mL of contrast agent. The goal is to adequately distend the bladder to avoid missing injuries.

The most common reason for false-negative cystographic results is failure to instill enough contrast material. Once the bladder is filled, clamp the catheter and obtain a KUB radiograph (Fig. 82.7). After ensuring adequacy of the contrast film, unclamp the catheter, allow the bladder to drain, and obtain a postevacuation film. Extraperitoneal rupture appears as a flamelike area of contrast material confined to the pelvis, often extending lateral to the bladder (Fig. 82.8). In cases of intraperitoneal rupture, contrast material outlines the bowel and other structures in the peritoneal cavity (Fig. 82.9). Using

than 11 years, calculate the appropriate amount of contrast agent in milliliters with the following formula: 
\[
\text{(age in years}/2) \times 30.
\]
If a bladder contraction occurs before the instillation of 400 mL of contrast material (as evidenced by the contrast level rising in the syringe), wait for the contraction

Fig. 82.7  A, Normal retrograde cystogram. Note the complete retrograde filling of the bladder via a Foley catheter. B, Normal retrograde cystogram. Note the complete evacuation of contrast material on the postvoid film.
the baseline film for comparison, carefully scrutinize the postevacuation film for any subtle areas of extravasation not seen on the contrast-distended view. For retrograde CT cystography, the bladder is filled in an identical manner. Do not simply clamp the Foley catheter and rely on passive filling of the bladder by intravenously administered contrast material for CT cystography. Multiple studies have demonstrated missed injuries with this approach. A postevacuation film is not necessary with retrograde CT cystography.

URETER

The diagnosis of ureteral injury is elusive. Intravenous pyelography has long been the test of choice, although its reported sensitivity is highly variable. CT imaging has gained popularity of late and is often indicated for identification of related injuries. In cases of suspected ureteral or renal pelvis disruption, additional delayed CT images (obtained 10 minutes after injection of contrast agent) are indicated to allow time for the intravenous contrast material to be excreted by the kidneys (Fig. 82.10). If operative exploration is indicated, the ureters may be directly evaluated in the surgical suite. When the diagnosis remains in doubt, retrograde pyelography may be useful.

KIDNEY

Renal imaging is indicated in all patients with penetrating trauma proximate to the kidneys and in those with blunt injuries and gross hematuria or microscopic hematuria with shock (defined as systolic blood pressure lower than 90 mm Hg). Additional relative indications include a significant decelerating mechanism, such as a high-speed motor vehicle collision or a fall from a height. The imaging study of choice is CT scanning with intravenous contrast enhancement. If injury to the collecting system is suspected, additional cuts should be obtained 10 minutes after injection of the contrast agent. Intravenous pyelography has been used extensively in the past but has largely been supplanted by CT.

In an unstable patient requiring immediate laparotomy, a “one-shot” intravenous pyelogram obtained in the operating room has some utility. Although this limited study does not provide sufficient sensitivity to exclude all clinically important renal injuries, it will demonstrate major renal disruption and confirm the presence of a functioning contralateral kidney. This study is accomplished by obtaining a KUB radiograph 10 minutes after rapid intravenous bolus injection of contrast material (2 mL/kg). Angiography performed on an emergency basis can be both diagnostic and therapeutic, but it is time-consuming and impractical in many centers. Ultrasonography lacks sensitivity in visualizing renal trauma and should not be relied on to exclude significant injury.

Note the presence or absence of any abnormalities that suggest genitourinary injury. In blunt trauma patients, such abnormalities include the following:

- Flank tenderness, bruising, or swelling
- The presence (and type) of a pelvic fracture
- Blood at the urethral meatus
- Ecchymosis or hematoma involving the penis, scrotum, or perineum

In patients with penetrating trauma, note whether the injury trajectory occurs in proximity to the genitourinary tract. Document the presence or absence of hematuria in the initial urine specimen.

Because genitourinary injuries are rarely life-threatening, initial assessment of a multiply injured patient is focused on rapid identification of potentially life-threatening injuries with prompt intervention to preserve life. During the initial resuscitation, note any findings, such as gross hematuria or an unstable pelvic fracture, that may herald genitourinary injury so that the appropriate investigation may be undertaken once the patient has been stabilized.

Except in the rare instance of a shattered kidney or major renal vascular laceration with significant hemorrhage, genitourinary injuries seldom pose a threat to life. Therefore, in a multiply injured patient, evaluation for genitourinary injury is deferred until other, potentially life-threatening injuries are excluded and the patient’s condition is stabilized. During the initial evaluation and stabilization, the emergency physician should note any findings that may herald genitourinary injury so that the appropriate investigation can be undertaken once the immediately life-threatening conditions have

Fig. 82.10 Injury to the collecting system of the left kidney. This delayed image demonstrates extravasation of contrast material from the renal pelvis.
been addressed. The patient should not receive any oral fluids until the need for operative intervention has been excluded. Intravenous fluids and analgesics may be administered as needed.

**EXTERNAL GENITALIA INJURIES**

Bleeding should be controlled with direct pressure. An amputated penis should be wrapped in saline-moistened gauze and placed in a sealed plastic bag, which is then placed on ice in a second plastic bag until reimplantation.

Any constricting devices should be removed promptly. This may be accomplished by unwinding a hair tourniquet, cutting a tight-fitting constricting ring or band, or wrapping a string or Penrose drain around the penis distal to the object to decrease swelling and facilitate removal. Liberal use of a water-based lubricant may be beneficial. After significant underlying injury has been excluded, copiously irrigate any superficial lacerations of the scrotum or penis and close with absorbable suture.

Zipper entrapment injuries are managed by infiltrating the affected area with 1% plain lidocaine followed by the application of mineral oil and carefully “unzipping” the zipper. If this fails, cut the slide bar of the zipper with an orthopedic pin cutter and gently pull the teeth apart.

Traumatic testicular torsion and displacement are treated surgically. All but the most superficial penetrating injuries to the external genitalia require operative exploration, especially those that violate the corpora cavernosa. Prompt surgical exploration plus repair of penile fractures minimizes the late complications of penile curvature, erectile dysfunction, and dyspareunia. Likewise, in patients with testicular rupture, early operative intervention maximizes the rate of testicular salvage. Reimplantation of an amputated penis should be performed as expeditiously as possible but has been successful after 16 hours of cold ischemia. The majority of women with vaginal injuries will require operative repair or washout to prevent significant morbidity and mortality.

**URETHRAL INJURIES**

In patients with a low-risk pelvic fracture (as defined previously) and no evidence of urethral injury on physical examination, it is reasonable to make a gentle attempt at passage of a Foley catheter. If any significant resistance is met, remove the catheter and obtain a retrograde urethrogram. If the retrograde urethrogram is normal, insert the catheter and inspect the initial output for evidence of hematuria.

If a urethral injury is suspected subsequent to successful placement of a Foley catheter, do not remove the catheter. A retrograde urethrogram may be obtained by inserting a small feeding tube alongside the catheter and proceeding as described previously. A urologist should be consulted for management of patients with abnormal retrograde urethrogram results or in cases of suspected urethral injury when a retrograde urethrogram cannot be obtained. In female patients, suspected urethral injury mandates urologic consultation; retrograde urethrography is not indicated in the emergency department (ED).

Optimal definitive management of urethral injuries depends on several factors, including the location (anterior or posterior) and severity (partial or complete) of the injury and the preference and expertise of the consulting urologist. Options vary from simple placement of a Foley catheter to allow a partial anterior urethral injury to heal by secondary intention to early endoscopic realignment or delayed urethroplasty of posterior urethral injuries. Frequently, placement of a suprapubic cystostomy tube is required to promote decompression of the bladder and divert urine from the healing urethral injury or anastomosis. Regardless of the approach, the ultimate goal is maintenance of urinary continence and sexual function.

**BLADDER INJURIES**

The Foley catheter should be irrigated as needed to clear any clots and ensure adequate drainage; the primary goal is to keep the bladder completely decompressed. Because bladder injuries are often associated with intraabdominal trauma, a diligent search for the latter should be undertaken in all patients with positive cystography results.

Operative repair is the rule for most intraperitoneal bladder ruptures. By contrast, the majority of extraperitoneal ruptures can be managed nonoperatively with catheter drainage alone. Exceptions include injuries involving the bladder neck, associated rectal or vaginal injuries, and patients requiring laparotomy for other indications.

**URETERAL INJURIES**

Identification and urologic consultation are the main priorities in the emergency management of ureteral injuries. Depending on the degree and location of the ureteral disruption, management options include cystoscopic stent placement or surgical repair over a stent. Urinary diversion may be required.

**KIDNEY INJURIES**

The need for operative intervention correlates with the severity of injury as classified by the American Association for the Surgery of Trauma organ injury severity scale for the kidney (Fig. 82.11 and Table 82.1). Most grade I and II injuries can
be managed nonoperatively, and nearly all grade V injuries (Fig. 82.12) require nephrectomy, which may be lifesaving in the rare case of exsanguinating hemorrhage from a renal vascular injury. Delayed nephrectomy may be indicated in the small subset of patients in whom hypertension or symptomatic renal infarction develops.27

### PEDIATRIC CONSIDERATIONS

It is somewhat controversial whether the criteria used to determine the need for renal imaging after blunt trauma in adults may be applied to children. One issue is whether the presence of microscopic hematuria in children warrants imaging even in the absence of shock. Some authors have recommended imaging in children when urine microscopy reveals more than 50 RBCs/HPF.29,30

Certainly, the criterion of shock as defined by a systolic blood pressure lower than 90 mm Hg is unhelpful in the pediatric population. Even age-specific definitions of hypotension are of little utility because children manifest shock differently than do adults. A recent study reviewing 720 consecutive pediatric patients with suspected renal trauma concluded that using the criteria of gross hematuria, shock, and significant deceleration injury can identify all cases of renal injury.31 However, like the definition of shock, “significant deceleration injury” was not well defined in this study.

For now, consensus guidelines recommend that hemodynamically stable children with blunt trauma undergo imaging if they have gross hematuria (i.e., more than 50 RBCs/HPF) on urine microscopy.31 All children with penetrating trauma in proximity to the kidneys warrant imaging.

### FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Most patients with significant genitourinary injuries require urgent or emergency urologic consultation in the ED. Additionally, many patients will have associated, nonurologic injuries that mandate trauma surgery or general surgery consultation. In the event that the appropriate specialists are unavailable, expeditious transfer to an appropriate referral center is indicated after the initial evaluation and stabilization.

A minority of hemodynamically stable patients with no other indications for admission may be considered for discharge from the ED after telephone consultation with the urologist who will see the patient for follow-up care. Such cases include minor lacerations, zipper injuries, and isolated partial anterior urethral injuries in the presence of a functioning Foley catheter. These patients should be counseled on the signs and symptoms of infection and Foley catheter dysfunction and be asked to return to the ED if these or any other concerning symptoms develop. Finally, make sure that they understand the importance of complying with the scheduled follow-up plan.

### FACTS AND FORMULAS

#### Pediatric Contrast Agent Dosage

The pediatric dose of a contrast agent for a retrograde urogram is 0.6 mL/kg to a maximum of 60 mL.

In patients younger than 11 years, calculate the appropriate amount of contrast agent in milliliters for retrograde cystography by using the formula (age in years + 2) × 30 to a maximum of 400 mL.
If a urethral injury is suspected subsequent to successful placement of a Foley catheter, a retrograde urethrogram may be obtained by injecting the contrast agent through a small feeding tube inserted alongside the catheter.

Cautions for the emergency physician:

• To avoid the risk of completing a partial urethral disruption, defer Foley catheter placement in a patient with a suspected urethral injury until urethral integrity is ensured by the retrograde urethrogram.

• Perform a careful rectal examination in all patients and a vaginal examination in women with a pelvic fracture to evaluate for rectal or vaginal lacerations.

• For computed tomographic cystography, do not simply clamp the Foley catheter and rely on passive filling of the bladder by intravenously administered contrast material. Multiple studies have demonstrated missed injuries with this approach.21-24

• In the setting of penetrating trauma, significant renal vascular injury may exist in the absence of hematuria.

Hip and Femur Injuries
Philip Bossart

KEY POINTS

- Most hip fractures result from ground-level falls in patients with osteoporosis.
- Patients with intertrochanteric fractures can experience significant blood loss into the thigh and may require fluid or blood resuscitation.
- Hip dislocations and femoral fractures are often caused by high-energy trauma such as motor vehicle collisions and falls from heights; associated injuries are therefore common and should always be looked for.
- Computed tomography is more sensitive than radiography in detecting fractures and can be considered when radiographs appear to be negative and clinical suspicion for fracture is present.
- Emergency physicians may relocate hip dislocations in the emergency department; however, most hip and femoral fractures require orthopedic consultation and operative repair.

EPIDEMIOLOGY

Approximately 300,000 hip fractures occur each year in the United States, and this number is projected to increase significantly as the population ages. The major cause of hip fractures is ground-level falls in elderly patients with osteoporosis. Hip injuries are a major cause of morbidity and mortality, especially in the elderly, in whom 1-year mortality after a hip fracture is approximately 25%. Femoral shaft and distal femoral fractures are usually the result of high-energy trauma such as motor vehicle collisions and falls from heights, and thus open wounds and associated traumatic injuries are common.

PATHOPHYSIOLOGY

The leading cause of hip fractures is falls in elderly people with underlying osteoporosis. Osteoporosis is a common condition in the elderly, and its incidence increases with advancing age. After about the age of 30, bone resorption slowly begins to exceed bone formation, and as a result bone mass and bone strength lessen. The lifetime risk of fracturing a hip is about 17% in white women and 5% in white men.

The major cause of hip dislocations is motor vehicle collisions. A great deal of force is required to dislocate a hip, and thus associated injuries are common. Up to 88% of hip dislocations will be accompanied by an associated fracture. Patients with hip dislocations have about a 25% risk for osteoarthritis and a 20% risk for avascular necrosis. In addition, sciatic nerve injuries occur in approximately 10% to 14% of patients with posterior hip dislocations. These risks may be decreased by prompt diagnosis and treatment in the emergency department (ED).

Osteonecrosis (also known as aseptic necrosis, ischemic necrosis, or avascular necrosis) may be caused by acute disruption of the blood supply to the femoral head as a result of a hip fracture or dislocation. Fractures of the femoral neck can also disrupt the blood supply and result in osteonecrosis. Other causes are sickle cell disease, barotrauma, radiation therapy, chemotherapy, atherosclerosis, and Gaucher disease. Associated conditions include steroid use, excessive alcohol consumption, smoking, connective tissue diseases, pancreatitis, and chronic liver and renal diseases. The incidence of osteonecrosis after hip dislocation depends on the degree of trauma involved and the duration of the dislocation. Some data suggest that reduction of the hip within 6 hours after dislocation decreases the incidence of osteonecrosis. Therefore, every effort must be made to relocate dislocated hips as soon as possible. Femoral neck fractures are also associated with a high incidence of osteonecrosis. It is thought that the synovial fluid around the fracture site interferes with normal bone healing. Intertrochanteric fractures and other more distal fractures of the femur are rarely complicated by osteonecrosis.

ANATOMY

The hip joint is a ball-and-socket articulation located between the femoral head and the acetabulum. The ligamentum teres, the capsular ligaments, and the proximal muscles of the leg make the hip a stable joint that requires very strong force to dislocate it. The femur is the largest and strongest bone in the body. The femoral neck is about 8 to 10 cm in length. The intertrochanteric line is an oblique line that connects the greater trochanter and the lesser trochanter and marks the junction of the femoral neck and the shaft.

The muscles of abduction (gluteus medius and gluteus minimus) insert on the laterally located greater trochanter, and the muscles of flexion (iliopsoas) insert on the medially located lesser trochanter. The major blood supply to the head...
and neck of the femur is the medial and lateral circumflex arteries, which are branches of the femoral artery.

The hip region has approximately 18 bursae. The most common source of hip pain and inflammation is the deep trochanteric bursa, which lies between the gluteus maximus and the greater trochanter.

**PRESENTING SIGNS AND SYMPTOMS**

Pain is the most common complaint in patients with hip problems. The location and character of the pain are very helpful in making a diagnosis. Increased pain during and after weight bearing and improvement with rest suggest a structural joint problem such as osteoarthritis. Constant pain, unrelated to use, suggests an infectious, inflammatory, or neoplastic process.

Lateral hip pain, especially with tenderness over the greater trochanter, suggests trochanteric bursitis. Lateral hip pain with paresthesias suggests meralgia paresthetica—lateral femoral cutaneous nerve entrapment. This condition is characterized by a local area of pain (often burning or dysesthesia) that is not influenced by direct pressure on the hip or back movement.

Anterior hip or groin pain made worse by joint motion suggests a problem with the hip joint, such as osteonecrosis, occult fracture, synovitis, or a septic joint. Anterior hip pain that is not made worse by hip motion or weight bearing suggests an inguinal hernia, lower abdominal pathology, or referred lumbar nerve root pain. Posterior hip pain suggests sacroiliac joint inflammation, lumbar radiculopathy, or herpes zoster. Anterior thigh pain may be secondary to injury to the hip joint or femur, stress fracture of the femoral neck, or lumbar radiculopathy.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

See Box 83.1.

**DIAGNOSTIC TESTING**

Anteroposterior (AP) and lateral radiographs of the hip are usually sufficient to diagnose hip dislocations and fractures.

**BOX 83.1 Differential Diagnosis of Hip Pain**

- Bursitis
- Osteoarthritis
- Hip dislocation
- Hip fracture
- Meralgia paresthetica
- Lumbar radiculopathy
- Osteonecrosis
- Acute synovitis
- Septic arthritis
- Herpes zoster
- Stress fracture of the femoral neck
- Aortoiliac occlusive disease
- Sacroiliac joint disease

For the AP view, the patient is placed supine with about 15 degrees of internal rotation of the feet. For the lateral view, the patient is placed supine with the uninvolved hip flexed and abducted. The radiograph cassette is placed against the lateral aspect of the affected leg, and the x-ray beam is directed horizontally toward the groin with 20 degrees of cephalic tilt.

Frog-leg views of the pelvis should not be ordered if hip fracture or dislocation is a possibility.

**HIP FRACTURES**

Hip fractures are classified as intracapsular or extracapsular. Intracapsular fractures include femoral head and femoral neck fractures (Fig. 83.1). These fractures are further categorized as either displaced or nondisplaced. Extracapsular fractures include intertrochanteric and subtrochanteric fractures, as well as the less common greater and lesser trochanteric fractures. These fractures can be further categorized by the degree of comminution.
FEMORAL HEAD FRACTURES
These relatively uncommon fractures usually occur in conjunction with hip dislocations in young people involved in motor vehicle collisions. Because these fractures may not be visualized on plain radiographs, computed tomography or magnetic resonance imaging may be necessary for diagnosis.

FEMORAL NECK FRACTURES
Fractures of the femoral neck, which is located between the femoral head and the trochanters, occur within the joint capsule and include subcapital fractures (fractures through the fused epiphyseal plate). These fractures are common and usually occur secondary to ground-level falls in older patients with osteoporosis and in young people involved in motor vehicle collisions.

This area of the femur has relatively little cancellous bone and very thin or absent periosteum; in addition, blood supply to the femoral head may be disrupted. As a result, degenerative changes involving the femoral head and frank avascular necrosis are common after these fractures.8

Because patients may be able to bear weight with some of these fractures, radiologic examination is important even if the patient is able to walk. Most femoral neck fractures can be treated by open reduction and internal fixation. Early surgical correction, usually within 12 hours, reduces the incidence of aseptic necrosis.

INTERTROCHANTERIC FRACTURES
Intertrochanteric fractures are extracapsular injuries and are the most common type of hip fracture. The majority occur in elderly patients with osteoporosis as a result of ground-level falls. About 80% are comminuted fractures. Because patients cannot bear weight, the diagnosis is probably evident clinically and usually easily confirmed with an AP radiographic view of the hip.

Patients with intertrochanteric fractures may lose as much as 1 to 2 L of blood, and therefore intravenous crystalloid infusion or blood transfusion may be necessary. Affected patients are typically elderly and frail; ED evaluation includes determining the reason for the fall (e.g., syncope, near-syncope, transient ischemic attack), as well as evaluation for other significant medical problems. The treatment of choice is surgical repair; however, because avascular necrosis is uncommon, surgery does not have to be performed immediately. Medical and postoperative complications are common, and about one third of these patients die within 1 year of the injury.

GREATER TROCHANTERIC FRACTURES
Fractures of the greater trochanter are uncommon. In adults they are generally the result of direct trauma; in children they are usually secondary to muscle avulsion. These fractures may be difficult to visualize on radiographs. Fractures caused by direct trauma are generally comminuted but not displaced; those caused by avulsion are usually displaced but not comminuted.

If displacement is greater than 1 cm, open reduction with internal fixation is often recommended. However, most of these fractures are generally minimally displaced and do not need surgery. If plain radiographs are uninformative, computed tomography or magnetic resonance imaging may be needed to make the diagnosis.

LESSER TROCHANTERIC FRACTURES
Fractures of the lesser trochanter typically occur in people younger than 20 years. If they occur in adults, a pathologic fracture should be suspected. The usual mechanism is forceful contraction of the iliopsoas muscle during strenuous activity. Patients are unable to lift the affected leg when in the sitting position. Treatment is usually bed rest.

SUBTROCHANTERIC FRACTURES
Subtrochanteric fractures are defined as fractures between the lesser trochanter and a point 5 cm distally. They are associated with severe trauma in young people or mild trauma in people with pathologic bone disease. Like intertrochanteric and mid-shaft femoral fractures, these fractures can be associated with significant blood loss. In addition, associated injury to the profunda femoris artery, branches of the lateral circumflex artery, the lateral femoral cutaneous nerve, and the femoral nerve is possible. If the patient has severe swelling in the proximal part of the thigh, angiography or duplex scanning should be performed to look for a vascular injury.

Treatment consists of open reduction and internal fixation. Because of the large stress forces in this area, nonunion is a relatively common complication.

FEMORAL SHAFT FRACTURES
The diagnosis of femoral shaft fractures is usually obvious on physical examination because of marked deformity and tenderness. These fractures most commonly occur after high-energy injuries such as motor vehicle collisions and falls, and thus associated injuries are common and must be carefully searched for.

If the fracture is associated with an open wound, the wound should be irrigated and covered with moist sterile dressings. Treatment of small, relatively clean wounds includes administration of a first-generation cephalosporin. An aminoglycoside should be given if more extensive soft tissue injury is present.

Because associated fractures in the hip and knee are common, radiographs should be obtained. Blood loss can be significant, but associated neurovascular injuries are rare. On average, these patients lose about 2 to 3 units of blood, and about 50% will require blood transfusions.

Traction devices should be removed when patients arrive at the ED, but limb immobilization should be maintained.

Treatment includes internal fixation with intramedullary rods. Severely comminuted fractures may be treated by closed reduction. In general, patients do better if the fractures are stabilized within 24 hours of injury. Early stabilization is associated with early patient mobilization and therefore less risk for the development of deep vein thrombosis, pressure ulcers, and pneumonia. Fat embolism syndrome is a possible complication. This condition is manifested by signs of pulmonary or central nervous system dysfunction, fever, and rash starting about 12 to 72 hours following the injury. In almost all cases, the fractures will have healed and the patients will be functional in 6 months. Nonunion is rare.

DISTAL FEMORAL FRACTURES
Fractures of the distal end of the femur tend to occur in older patients with severe osteoporosis or in young people with multiple trauma. Supracondylar and intercondylar fractures of the femur are difficult to treat. They are generally unstable and often comminuted. Most are treated operatively.
However, malunion, nonunion, and infections are relatively common.

**STRESS FRACTURES**

Stress fractures occur when normal bone is subjected to repeated stress. The bone fails because osteoblasts are unable to lay down new bone fast enough. Symptoms of a femoral neck stress fracture can be very mild pain only. Consequently, the injury may be mistaken for a muscle strain or arthritis. Pain is typically felt in the groin and medial aspect of the thigh, is worse with use, and may make weight bearing very painful or impossible.

Findings on physical examination are usually normal, except perhaps some pain at the extremes of hip flexion and internal rotation. Because plain films are generally unrevealing until 14 days after the injury, computed tomography or magnetic resonance imaging may be needed to make the diagnosis. This condition is often bilateral, so any pain in the other hip needs evaluation as well.

**HIP DISLOCATIONS**

In approximately 90% of hip dislocations, the femoral head is posterior to the acetabulum. Typically, posterior hip dislocations occur when the knee hits the dashboard during a motor vehicle collision. In posterior hip dislocations the limb is adducted, internally rotated, and shortened. In anterior dislocations the limb is abducted, externally rotated, and shortened.

**POSTERIOR HIP DISLOCATIONS**

Several techniques for reducing posterior hip dislocations have been described in the literature. All these methods require adequate sedation and analgesia. The Stimson method requires the patient to lie with the legs hanging over the edge of the bed. This position is seldom practical in a trauma patient, however.4

The Allis technique involves keeping the patient supine on the bed. The hip is then flexed to 90 degrees and upward traction is applied with some gentle internal and external rotation. It is usually necessary to stand on the bed over the patient to perform this technique. An assistant stabilizes the pelvis and may apply some lateral force to the leg.

The Whistler technique involves lying the patient supine on the bed with the knees flexed about 130 degrees.5 An assistant stabilizes the pelvis while the operator stands on the side of the bed near the affected hip. The operator places an arm under the knee on the leg with the dislocation and then grips the top of the other knee. The other hand stabilizes the patient’s ankle. The operator then raises up the arm by using the patient’s knee as a lever in an attempt to relocate the hip. After reduction, the legs are immobilized in slight abduction with a pillow between the knees, and the patient should be sent for radiographs and hospital admission.

**ANTERIOR HIP DISLOCATIONS**

A modification of the Allis maneuver can be used to relocate anterior hip dislocations. The patient is placed supine and an assistant stabilizes the pelvis and applies lateral force to the affected thigh. Traction is then applied along the long axis of the femur with the hip slightly flexed. Gentle leg adduction and internal rotation may facilitate the reduction.

Postreduction care is the same as for posterior hip dislocations.

**PROSTHETIC HIP DISLOCATIONS**

A patient with a hip arthroplasty may dislocate the hip with minimal force. Frequently, a minor twisting motion is all that it takes. As with native hips, the majority of these dislocations are posterior. The reduction methods are the same as with a native hip. Orthopedic consultation should be considered. Because aseptic necrosis is not an issue, there is no urgency to reduce the hip. Unlike patients without artificial hips, these patients will often not require hospitalization after reduction.

**RED FLAGS**

- It is important to look for acetabular fractures before performing closed reduction of a hip dislocation.
- On average, patients with femoral shaft fractures lose about 2 to 3 units of blood at the fracture site, and about half of these patients will require blood transfusions.
- Hip dislocation or fracture in a young person is strong evidence of serious multisystem trauma.

**TIPS AND TRICKS**

- Consider avascular necrosis in patients with nontraumatic hip, thigh, or knee pain.
- If hip pain prevents weight bearing and plain films do not reveal a fracture, perform computed tomography or magnetic resonance imaging to rule out a fracture.

**ULTRASOUND-GUIDED FEMORAL NERVE BLOCK**

Pain relief for hip fractures and femoral shaft fractures can be achieved with ultrasound-guided femoral nerve blocks.10 Contraindications to this procedure include hypersensitivity to the local anesthetic and infections near the injection site. In addition, patients with neurologic deficits in the affected leg or those at risk for compartment syndrome should not have a femoral nerve block performed because it may make it difficult to detect new or worsening neurologic changes. A femoral nerve block is also relatively contraindicated in patients taking anticoagulants or with a bleeding diathesis.

Because high energy is generally required to dislocate a hip, associated injuries are common.11 Ligamentous knee injuries, acetabular and femoral fractures, and sciatic nerve palsies should be considered. If an associated fracture is not clearly seen on plain films, a computed tomography scan should be ordered.

Posterior dislocations are likely to cause a fracture of the inferior aspect of the femoral head and may cause injury to the sciatic nerve.12 Anterior dislocations are associated with fractures of the anterior femoral head and also with vascular injuries.
Hip dislocations are orthopedic emergencies. Reduction should be performed as soon as possible because the incidence of avascular necrosis, traumatic arthritis, and joint instability increases with the length of time that the hip is dislocated. In addition, orthopedic consultation should be obtained.

Hip relocations require procedural sedation in the ED or general anesthesia in the operating room.

Knee and Lower Leg Injuries

Christy Hopkins

KEY POINTS

- Knee dislocations are associated with a high risk for neurovascular injury and constitute an orthopedic emergency.
- A grossly unstable knee should be assumed to have been dislocated.
- Patients with fractures or dislocations of the knee and lower extremity and neurovascular compromise should undergo emergency reduction or realignment before any radiographic evaluation.
- Patients discharged home in knee immobilizers with stable injuries should be instructed to remove the device several times a day and perform range-of-motion and quadriceps-strengthening exercises.
- The cast or splint should be removed from any patient with increasing pain after a lower leg fracture to allow careful assessment of neurovascular status and evaluation of the lower leg compartments.

EPIDEMIOLOGY

Knee and lower leg injuries are common orthopedic problems seen in the emergency department (ED). This chapter divides such injuries into discussions of traumatic injuries (soft tissue and cartilaginous injuries, dislocations, and fractures), overuse injuries, and other disorders of the knee and lower part of the leg.

PATHOPHYSIOLOGY

KNEE Anatomy

The knee is the largest and most complex joint in the body. Injuries to this joint are common, so a clear understanding of the anatomy and pathophysiology of the knee is essential for appropriate evaluation, diagnosis, and treatment of disorders in this area.

The knee has a wide range of motion, including flexion, extension, abduction, adduction, and internal and external rotation. Three different articulations are present in the knee: the patellofemoral articulation (anterior) and articulations between the lateral and medial tibial and femoral condyles. In full extension, the stabilizing ligaments of the knee are tight and prevent rotary motion of the knee. Beyond 20 degrees of flexion, the ligaments are relaxed and allow axial rotation of the joint.

Knee stability is provided solely by ligaments and tendons in and around the joint (Fig. 84.1). The knee joint is encapsulated by fibrous connective tissue lined by a synovial membrane. The knee capsule is continuous with the suprapatellar bursa, which expands when a joint effusion is present.

The popliteal fossa contains the popliteal artery and vein and the peroneal and tibial nerves. The popliteal fossa is delineated laterally by the biceps femoris muscle, medially by the semimembranosus and semitendinosus muscles, and inferiorly by the gastrocnemius muscle.

The popliteal artery is a continuation of the femoral artery after it leaves the adductor hiatus. It gives rise to the geniculate arteries, which form a rich vascular anastomosis around the knee, and divides to form the anterior and posterior tibial arteries at the level of the tibial tubercle. The popliteal artery is immobilized proximally and distally within the popliteal fossa, which predisposes it to vascular injury in the setting of traumatic knee injuries.

The tibial nerve and common peroneal nerve (a branch of the tibial nerve) innervate the knee. Because the tibial nerve is not immobilized proximally, it is less likely than the popliteal artery to be injured in the setting of joint disruption. The common peroneal nerve travels around the head of the fibula and divides into the deep and superficial peroneal nerves.

Evaluation

Key aspects of evaluation of knee are listed in Box 84.1. In general, evaluation of knee complaints should also include an examination of the hip and back to prevent overlooking a source of pain referred to the lower extremity.

During evaluation, the point of maximal tenderness should be assessed last. Specific tests for evaluating ligamentous and meniscal injuries are detailed in Table 84.1. Comparison with the uninjured or normal knee is helpful, especially for assessment of ligamentous laxity.

Joint pain or swelling may limit full evaluation of the knee in the acute setting. Patients with limited evaluations should...
undergo immobilization and follow-up examination within 7 days. Key physical findings are listed in discussions of specific disorders later in the chapter.

**Diagnostic Testing**

Because acute injuries to the knee commonly involve soft tissue, plain radiographic examination is not always indicated. The Ottawa Knee Rules1 (Box 84.2) and the Pittsburgh Knee Rules2 (Box 84.3) are useful guides to aid in the decision of whether to order plain radiographs. Both criteria are sensitive for fractures, but the Pittsburgh criteria are more specific and can be applied to both children and adults.

If plain radiographs are indicated, a minimum of an anteroposterior (AP) and a lateral view should be obtained. Oblique radiographs are helpful for detecting subtle tibial plateau fractures. The intercondylar or tunnel view is helpful in evaluating tibial spine fractures and osteochondral defects (Fig. 84.2). Assessment of the patellofemoral joint and evaluation for the presence of patellar tilt (increased propensity for patellar subluxation or dislocation) can be done with the Merchant or sunrise view (Fig. 84.3). Comparison radiographs of the unaffected extremity are helpful in discerning problems in skeletally immature patients.

When describing the knee radiograph, the examiner should note the alignment and joint spacing of the femoral condyles in relation to the tibial plateau. Narrowing of the joint space (particularly in weight-bearing views) indicates articular cartilaginous and meniscal degeneration. The patella should be examined for possible fractures (in the event of a direct blow to the anterior aspect of the knee) and the presence of a bipartite or tripartite patella. Significant joint effusions are evident as a water-density radiolucency on the lateral view, anterior to the distal end of the femur.4 Effusions seen shortly after injury are suggestive of anterior cruciate ligament (ACL) or posterior cruciate ligament (PCL) tears, tibial plateau fractures, femoral condyle fractures, or patellar fractures.4

In the setting of acute injuries, radiographs should be examined for the presence of fractures involving the tibial plateau (depression fracture) or tibial spine (suggesting rupture of the ACL). Second fractures are avulsion fractures of the lateral tibial plateau at the site of attachment of the lateral capsular ligament. These fractures are associated with ACL and meniscal injuries. The presence of posterior opaque bodies should

### BOX 84.1 Evaluation of the Knee

#### History
- **Mechanism of injury:**
  - Direction and type of force (high or low energy)
  - Position of the extremity at the time of injury
- **Nature and duration of symptoms**
- **Previous injuries**
- **Previous surgical procedures**
- **Associated complaints**
- **Joint effusion**
- **Locking of the joint**
- **Ability to ambulate**
- **Associated injuries**

#### Physical Examination
- **Inspection:**
  - Deformity, ecchymosis, edema, cutaneous lesions
  - Joint effusions
  - Previous scars
  - Gait and functional range of motion
  - Neurovascular status
- **Palpation:**
  - Extensor mechanism: quadriceps tendon, patella, patellar tendon, tibial tubercle (tendinitis, prepatellar bursitis, knee effusion, Osgood-Schlatter disease)
  - Femoral or tibial epiphysis in adolescents (physeal fractures)
  - Joint line (meniscal and/or collateral ligament injuries)
  - Posterior aspect of the knee (popliteal cyst or pseudoaneurysm)
  - Neurovascular status
- **Range of motion:**
  - Flexion or extension
  - Internal or external rotation
  - Active straight leg raise
- **Stability testing:**
  - Anterior or posterior stability (cruciate ligaments)
  - Medial or lateral stability (collateral ligaments)

**BOX 84.2 Ottawa Knee Rules**

Radiographs indicated if any one of the following is present:
- Age 55 years or older
- Tenderness at the head of the fibula
- Isolated tenderness of the patella
- Inability to flex the knee to 90 degrees
- Inability to bear weight for four steps both immediately after the injury and in the emergency department

---

**BOX 84.3 Pittsburgh Knee Rules**

Radiographs are indicated if the patient sustained a fall or a blunt trauma mechanism and one of the following two conditions is present:
- The patient is younger than 12 or older than 50 years.
- The patient is unable to walk four weight-bearing steps in the emergency department.

Fig. 84.2 Knee radiograph, tunnel or intercondylar view, showing an osteochondritis dissecans lesion (arrows).

Fig. 84.3 Merchant view of the knee showing patellar tilt and subluxation.

Fig. 84.4 Cross section of the lower extremity at the level of the calf. (From Khatri VP, Asensio JA. Operative surgery manual. Philadelphia: Saunders; 2003.)

also be noted. These may be fabellae (congenital sesamoid) or loose bodies. More than 75% of loose bodies originate from osteochondral lesions. Occult fractures that are commonly missed on plain radiographs include patellar, tibial plateau, fibular head, and Segond fractures.

Musculoskeletal ultrasound techniques can be used to diagnose ACL and PCL tears and may be helpful in the diagnosis of meniscal injuries. Magnetic resonance imaging (MRI) can be used to confirm suspected meniscal injuries, ligamentous disruptions, osteochondral lesions, and occult fractures; however, it is rarely indicated in the acute setting. Computed tomography (CT) is helpful for establishing the extent of certain fractures (e.g., tibial plateau fractures) and is often more readily available than MRI.

**LOWER LEG**

**Anatomy**
The lower part of the leg contains the tibia and fibula. The tibia is the only weight-bearing bone in this part of the leg and is the most commonly fractured long bone in the body. Its superficial course predisposes it to a higher incidence of open fractures. The two bones are bound together by the superior and inferior tibiofibular joint along with an interosseous membrane. The interosseous membrane aids in stability of the ankle mortise.

The thigh muscles attach to the upper part of the tibia and lend stability to the knee joint. The muscles of the lower part of the leg, which are enclosed by fascia, can be divided into four compartments: anterior, posterior, deep posterior, and lateral (Fig. 84.4). Specific motor and sensory nerve distributions are listed by compartment in Table 84.2.

**Evaluation**
A directed history of the traumatic events, duration of symptoms, and exacerbating events or activities is necessary to assess lower leg injuries. Examination of lower leg complaints should include an evaluation of the back, hips, knee, and ankle to assess for pain referred to the lower part of the leg or associated injuries.

Thorough assessment of skin integrity, neurovascular status, and the leg compartments is essential in the evaluation of any traumatic lower leg injury. The point of maximal tenderness should be evaluated last.

**Diagnostic Testing**
Imaging of the lower part of the leg should include the joint above and the joint below the injury. Oblique views are useful for detecting tibial plateau fractures, which may not be seen on routine views.
DISLOCATIONS AND FRACTURES

DISLOCATIONS
Knee Dislocations

Knee dislocations are relatively uncommon and represent, at most, 0.2% of all orthopedic injuries. They require disruption of at least three of the four major ligaments of the knee. Common mechanisms include traffic accidents, sporting injuries, or simple mechanical falls. Dislocations are classified on the basis of the direction of tibial movement in relation to the femur. Anterior and posterior dislocations account for approximately 70% of all knee dislocations. Knee dislocations may also have associated intraarticular fractures involving the tibial plateau or femoral condyles.6

Knee dislocations are associated with a high risk for neurovascular injury and should be considered an orthopedic emergency. The neurovascular bundle runs posterior to the bony and ligamentous structures in the popliteal fossa. The popliteal artery and nerve are fixed in the fibrous tunnel of the adductor magnus muscle proximally and traverse the fibrous arch of the soleus muscle and interosseous membrane distally. The relative immobility of the neurovascular bundle makes it susceptible to injury. The popliteal artery may be injured in up to 14% of all knee dislocations (Fig. 84.5). Traction injuries to the common peroneal and, less commonly, to the tibial nerve may also be present.6

A grossly unstable knee after a traumatic injury should be assumed to be a reduced dislocation until proved otherwise. Any patient suspected of having sustained a knee dislocation should undergo a careful neurovascular examination. Anterior and posterior dislocations have a higher incidence of vascular injury. Vascular compromise in a dislocated knee requires immediate reduction.

Neurovascular status should be documented before and after reduction. All patients with a suspected or confirmed knee dislocation should have the ankle-brachial index (ABI) calculated. An ABI of less than 0.9 has high predictive value for a vascular injury, and such patients should undergo either CT or traditional angiography. Patients with normal findings on vascular examination and an ABI lower than 0.9 should be observed for at least 24 hours with neurovascular checks every 2 to 3 hours.4 Prompt diagnosis of vascular injury is essential given the chance of development of progressive distal ischemia. When injury to the popliteal artery has occurred, patient outcome is directly related to the duration of ischemia.

Standard AP and lateral radiographs are adequate for initial evaluation of knee dislocations. After appropriate analgesia and sedation, emergency reduction of the dislocated knee should be attempted. Longitudinal traction on the tibia (to free it from the femur) should be followed with a force in the opposite direction of the dislocation. The rotary components should also be corrected to restore normal leg alignment. After reduction, the knee should be immobilized in 15 to 20 degrees of flexion.4 Orthopedic consultation in the ED is mandatory for all suspected and confirmed knee dislocations.

Patellar Dislocation

The patella normally articulates in the groove between the femoral condyles. The vastus medialis, medial and lateral patellofemoral, and patellofibial ligaments and the medial retinaculum all stabilize the patella (Fig. 84.6).

The overall incidence of patellar dislocations is estimated to be 7 per 100,000 per year and as high as 31 per 100,000 per year in patients between the age of 10 and 19 years.7 Patellar dislocations most commonly occur when a varus force is applied to a flexed knee or after forced contraction of a flexed quadriceps. Dislocations may be associated with meniscal tears, disruption of the medial collateral ligament, and osteochondral fractures.7

The patient may report that the knee “gave out,” followed by pain and swelling. Patients may not be able to bear weight on or flex the knee. An acute hemarthrosis is most commonly seen if an associated osteochondral fracture is present. A patellar apprehension test may be useful in a patient who reports a dislocation that resolved spontaneously. This test is performed by moving a nondisplaced patella laterally. The result is positive if the patient shows apprehension, senses pain, or feels a sensation of impending dislocation when the patella is moved laterally (Fig. 84.7). AP, lateral, and sunrise radiographs are adequate to evaluate for acute dislocations and associated fractures.

After proper sedation, the emergency physician (EP) should reduce a lateral patellar dislocation by flexing the hip and pushing medially on the patella while extending the knee. Postreduction radiographs are mandatory to rule out osteochondral fractures. Intraarticular, horizontal, and superior dislocations typically require open reduction. Dislocations associated with osteochondral fractures are generally treated surgically.

After reduction, the patient should be told to use conservative therapeutic measures, such as ice, elevation, and pain control. The knee should be placed in a straight leg immobilizer, and the patient can start progressive weight bearing when comfortable. Follow-up should be arranged within 1 to

Table 84.2 Peripheral Nerve Assessment of the Leg
2 weeks. Complications include persistent instability, subluxation, repeated dislocation, and osteoarthritis.

**Proximal Tibiofibular Joint Dislocations**

The proximal tibiofibular joint is a small joint between the head of the fibula and the inferior aspect of the lateral tibial condyle. Dislocations can be anterior (most common), posterior, or superior. This rare injury is seen more in adolescents and young adults. It is typically associated with motor vehicle crashes and sports such as skydiving and hang gliding.

Pain and tenderness are felt over the proximal tibiofibular joint. On physical examination the patient has worsening pain with inversion and eversion of the foot or flexion and extension of the ankle. Instability may be present when anterior or posterior pressure is applied to the fibular head. Peroneal nerve injury occurs in approximately 5% of these dislocations.
AP and lateral radiographs are indicated. A comparison view may be helpful to make the diagnosis. Radiographs may demonstrate lateral displacement of the fibular head or diastasis of the proximal ends of the tibia and fibula.

Tibiofibular dislocations are reduced by flexing the knee to 90 degrees and evertting and dorsiflexing the ankle while applying direct pressure to the head of the fibula. General anesthesia may be necessary. After reduction, the knee should be immobilized in extension or partial flexion. Posterior dislocations may be unstable, and recurrent subluxation may be seen. Degenerative joint disease and arthritis can develop after injury to this joint.  

FRACTURES

Patellar Fracture

The patella, the largest sesamoid bone in the body, is enveloped within the quadriceps tendon and articulates with the trochlear groove of the distal end of the femur. The superficial location of the patella makes it more susceptible to injury.

Patellar fractures account for approximately 1% of skeletal injuries and are the result of either a direct injury (dashboard injury) or an indirect injury (violent flexion). Indirect injuries result in an avulsion injury of the patella as a result of pull of the quadriceps muscle against resistance. Transverse patellar fractures are the most common type of fracture and are more likely to be displaced and be manifested as a disrupted extensor mechanism.

The patient usually has a swollen, painful knee. Patellar evaluation includes palpation for pain and bony disruption and assessment for extensor weakness. AP, lateral, and sunrise views of the knee should be obtained. A bipartite patella may be difficult to distinguish from a patellar fracture and is most often seen in the superolateral part of the patella. A high-riding patella, or a patella alta position, may signify disruption of the distal extensor mechanism; this is best visualized on AP and lateral views.

Acute treatment of patellar fractures consists of ice, elevation, pain control, and a straight leg knee immobilizer. Nonoperative intervention is considered for nondisplaced fractures (<3 to 4 mm) when the extensor mechanism is intact. Patients with a disrupted extensor mechanism should have immediate orthopedic consultation because these injuries are often repaired within 24 hours.

Proximal Tibial Fractures

Proximal tibial fractures include fractures above the tibial tuberosity.

TIBIAL PLATEAU FRACTURES

The proximal end of the tibia comprises the medial and lateral condyles, which make up approximately three fourths of the proximal tibial surface. The condyles ensure appropriate knee alignment, stability, and motion. Tibial plateau fractures account for about 1% of all proximal tibial fractures.

Tibial plateau fractures are caused by side loading secondary to either a varus or a valgus force combined with axial compression, which results in the femoral condyle impacting on the tibia. Common mechanisms are motor vehicle crashes, falls, and athletic activities such as skiing. A Segond fracture is bony avulsion of the lateral tibial plateau at the site of attachment of the lateral capsular ligament. This fracture is an important marker for ACL disruption and anterolateral rotary instability. Associated soft tissue injuries to the collateral ligaments, menisci, and neurovascular structures are common, although low-energy injuries (from athletic activities) usually result in less soft tissue damage.

Patients with tibial plateau fractures exhibit pain and swelling of the knee and hold their knee in a slightly flexed position. A valgus or varus deformity of the knee generally indicates a depressed fracture. Careful assessment of associated ipsilateral bony, soft tissue, and neurovascular status is essential given the high rate of association of such injuries with tibial plateau fractures.

AP, lateral, and oblique radiographs are necessary to evaluate tibial plateau fractures. In addition, a tibial plateau view is helpful in assessing the amount of depression present. CT with 2-mm cuts and three-dimensional reconstruction is useful to further investigate indeterminate plain films, evaluate fracture patterns, show the precise extent of articular depression, and assist in planning for optimal operative treatment.

Nonoperative treatment is indicated for minimal or nondisplaced fractures (<2 to 3 mm of articular incongruity), peripheral (submeniscal) fractures, and fractures in elderly, low-demand, or osteoporotic patients. Patients should not bear weight on the affected leg for 4 to 6 weeks.

Absolute indications for surgery are open fractures, arterial injuries, and compartment syndrome. Relative indications for surgery are displaced fractures leading to joint instability and depression of the plateau. The amount of depression that requires operative intervention is controversial and ranges from 3 to 10 mm; however, 3 mm is the usual cutoff in athletic patients.
TIBIAL SPINE FRACTURES Tibial eminence avulsion fractures occur most often in children 8 to 14 years of age but can be seen in skeletally mature patients as well. A fracture of the anterior tibial spine in children is equivalent to an ACL rupture in adults.

The intercondylar eminence, or tibial spine, is the central portion of the proximal tibial surface. Tibial spine injuries usually result from a hyperextension force with or without a valgus or rotational moment about the knee. The fracture may also occur after a direct blow to the distal end of the femur while the knee is flexed (Fig. 84.9).

Affected patients have a suggestive history and a painful, swollen knee. In most cases, patients are unable to fully extend the knee and exhibit an effusion, and findings on stability tests (Lachman, anterior drawer) are abnormal. The examiner should carefully evaluate such patients for associated ligamentous injuries.

Routine AP and lateral radiographs are adequate to define these fractures. CT is helpful for evaluating displacement, whereas MRI is superior in assessing any accompanying soft tissue injuries.

Fractures with little or no displacement should be immobilized in a long leg splint with the knee flexed at approximately 10 to 20 degrees. Displaced fractures necessitate orthopedic consultation because they may require closed reduction (if no ligamentous damage is present) or open or arthroscopic reduction with fixation of the fragments.10

SUBCONDYULAR FRACTURES Subcondylar fractures involve the proximal tibial metaphysis and are usually transverse or oblique. Isolated subcondylar fractures are rare, and such fractures are generally associated with tibial plateau fractures.

Routine AP and lateral radiographs are adequate for evaluation of subcondylar fractures. Acute management of these injuries involves ice, elevation, and immobilization in a long leg splint. Stable extraarticular nondisplaced transverse fractures are treated with a long leg cast for 8 weeks. Fractures that are comminuted or associated with a condylar component require open reduction and internal fixation.8

**Tibial Shaft Fractures** Tibial shaft fractures are the most common long-bone fractures, as well as the most common open long-bone fracture. They are commonly associated with a fibular fracture or ligamentous injury. The fibula remains intact in only 15% to 25% of tibial shaft fractures. These fractures are associated with a high incidence of infection, delayed union, nonunion, and malunion.

Tibial shaft fractures result from either direct (motor vehicle accidents) or indirect (rotary or compressive forces) trauma. High-energy direct injuries usually cause transverse or comminuted fractures (most common). Indirect trauma commonly results in spiral or oblique fractures (Fig. 84.10).

A good neurovascular examination is essential. Skin integrity should be noted, and documentation of the integrity of the peroneal nerve is mandatory, as is a thorough examination of the knee and ankle.

AP and lateral radiographs should be obtained and must include the knee and ankle in both views. Closed tibial shaft fractures are immobilized in a long leg posterior splint with 10 to 20 degrees of knee flexion. Closed tibial and fibula shaft fractures, especially if displaced, are at risk for the development of compartment syndrome. Such injuries may necessitate observation in the hospital. It is estimated that compartment syndrome may develop in approximately 8% of tibial diaphyseal fractures. Any patient discharged home from the ED with a closed tibial fracture should be educated about the signs of compartment syndrome.

Open fractures should be gently cleaned, dressed with sterile dressings, and placed in a splint while awaiting orthopedic consultation. Patients should receive prophylactic antibiotics and tetanus prophylaxis. Emergency reduction is necessary for injuries accompanied by neurovascular compromise. Nonunion or delayed union is more likely with fractures that are open, severely displaced, or comminuted or with fractures associated with severe soft tissue injuries or infections.11

**Proximal Fibular Fractures** Proximal fibular fractures are often seen in conjunction with tibial fractures. Isolated proximal fibular fractures are rare given that the fibula runs parallel to the tibia and is bound to the tibia via ligaments. These fractures may be associated with significant knee injuries.

Isolated proximal fibular fractures are treated with protected weight bearing. The EP must rule out other associated injuries, such as lateral collateral ligament injury, common peroneal nerve injury, arterial injuries, and Maisonneuve fractures.11

**Tibial Tuberosity Fractures** The tibial tubercle is a bony prominence that is found approximately 3 cm distal to the proximal articular surface of
the tibia and in line with the medial half of the patella. It is the insertion point of the extensor mechanism, and thus accurate reduction and healing of this structure are essential.

Tibial tubercle avulsion fractures are rare injuries. Although they can occur in adults, these fractures are more commonly seen in adolescents undergoing a growth spurt. Most fractures are the result of an indirect force delivered by an eccentric load. A sudden flexion force is applied while the knee is in flexion and the quadriceps is tightly contracted. The quadriceps resists the force, which causes avulsion of the tibial tubercle.

The physical findings depend on the extent of the injury. Swelling and tenderness are present over the anterior aspect of the tibia. A joint effusion may result from associated intraarticular injuries. The injured knee is usually held in 20 to 40 degrees of flexion secondary to hamstring spasm. In addition, the patient may not be able to extend the knee because of either pain or loss of the extensor mechanism.

Routine AP and lateral radiographs are useful for ruling out associated fractures (Fig. 84.11). Initial treatment is similar to that for both quadriceps and patellar tendon injuries. Minimally displaced fractures are treated conservatively. Displaced fractures frequently require open reduction and internal fixation.

Fig. 84.10 Radiographic examples of the three grades of severity of tibial fractures. A, Minor: spiral fracture caused by a simple slip and fall. B, Moderate: fracture in a pedestrian struck by a slowly moving vehicle. C, Major: fracture caused by a high-velocity motorcycle crash. (From Browner BD, Jupiter JB, Levine AM, et al. Skeletal trauma: basic science, management, and reconstruction. 3rd ed. Philadelphia: Saunders; 2003.)

SOFT TISSUE AND CARTILAGINOUS INJURIES

EXTENSOR MECHANISM INJURIES

The extensor mechanism of the knee is composed of the quadriceps muscles and tendon, the patella, the patellar tendon, and the tibial tubercle. Injuries can result from direct trauma (direct blow or laceration) or an indirect force (forced flexion of the knee). Rupture of the extensor mechanism is relatively uncommon in comparison with other injuries involving the knee joint.

QUADRICEPS AND PATELLAR TENDON INJURIES

The quadriceps tendon represents the convergence of the rectus femoris, vastus intermedius, vastus lateralis, and vastus medialis muscles. It inserts on the superior pole of the patella. The patellar tendon travels from the inferior pole of the patella to the tibial tubercle.

Quadriceps ruptures typically occur in patients older than 40 years. Rupture is usually the result of forced quadriceps contraction with a flexed knee, which loads the tendon. Direct blows and lacerations can also cause disruption of the tendon.
The most common site of rupture is at or near its insertion on the patella. Predisposing factors are listed in Box 84.4.

Patellar tendon ruptures are less common. Risk factors for patellar tendon rupture are similar to those for quadriceps rupture, with the exception that they generally occur in patients younger than 40 years. Most patellar tendon ruptures occur along the inferior pole of the patella.

Pain, swelling, and ecchymosis are usually localized to the superior pole (quadriceps tendon) or inferior pole (patellar tendon) of the patella. A defect in the patella or quadriceps tendon may be palpable on physical examination. Other physical findings include a low-riding patella (patella baja) with inferior retraction of the patella (quadriceps tendon rupture) or a high-riding patella (patella alta) with superior retraction of the patella (patellar tendon rupture). The integrity of the extensor mechanism should always be evaluated.

AP and lateral radiographs help define the patellar position (alta or baja) and rule out associated fractures. Ultrasound has also been shown to be useful in diagnosing quadriceps tears. MRI is helpful in the diagnosis of partial tears.

Orthopedic consultation in the ED is indicated for suspected injuries and complete ruptures. Initial treatment consists of ice, elevation, and a straight leg immobilizer. Partial tears are treated by immobilization for 4 to 6 weeks, whereas complete tears are treated surgically. Diagnosis is essential given the better outcomes with prompt referral and repair.

**LIGAMENTOUS AND MENISCAL INJURIES**

Knee stability depends on the static stability of the ligaments and the dynamic stability of the muscles. Injuries to the knee involve the following six common mechanisms: (1) valgus stress (laterally directed), (2) varus stress (medially directed), (3) hyperextension, (4) rotational stress, (5) direct anterior stress, and (6) direct posterior stress. These stressors, working in isolation or combination, may result in myriad of ligamentous, meniscal, or chondral injuries.12

Common mechanisms of ligamentous knee injuries are shown in Figure 84.12. Diagnosis is based on clinical

examination; plain radiographs are indicated if a fracture is suspected. MRI offers a direct, noninvasive view of the knee ligaments, menisci, and other soft tissue structures; however, it is rarely indicated in the ED setting.

Stability testing for ligamentous and meniscal injuries is outlined in Table 84.1 and Figures 84.13 to 84.16. Ligament function, mechanism of injury, diagnosis, and treatment are outlined in Table 84.3. Most ligamentous and meniscal injuries should be reevaluated by an orthopedist in 3 to 5 days.⁴

**MUSCLE STRAINS**

**Gastrocnemius Muscle Strain**

The gastrocnemius, soleus, and plantaris muscles form the posterior muscles of the calf. The tendon of the gastrocnemius muscle has two heads that arise from the posterior surfaces of the medial and lateral femoral condyles. The tendons of the gastrocnemius and soleus muscles form the Achilles tendon, which inserts on the posterior tubercle of the calcaneus. The gastrocnemius muscle acts primarily as a plantar flexor but also provides some passive support to the

---

**Fig. 84.13** Lachman test for anterior drawer instability. The test is done at 20 to 30 degrees of flexion. The examiner stabilizes the femur with one hand and draws the tibia anteriorly with the other hand. (From Browner BD, Jupiter JB, Levine AM, et al. Skeletal trauma: basic science, management, and reconstruction. 3rd ed. Philadelphia: Saunders; 2003.)

**Fig. 84.14** Anterior drawer test. The knee is placed in 90 degrees of flexion, the foot is stabilized with pressure toward the examination table, and the proximal end of the tibia is grasped and pulled forward. (From Brown JR, Trojan TH. Anterior and posterior cruciate ligament injuries. Prim Care 2004;31:925-56.)

**Fig. 84.15** Pivot shift test. With one hand the examiner flexes the hip to 45 degrees, extends the knee, and holds the heel. With the other hand the examiner holds the knee with the thumb behind the fibular head. The examiner then internally rotates the leg at the heel and applies valgus stress and flexion at the knee. (From Brown JR, Trojan TH. Anterior and posterior cruciate ligament injuries. Prim Care 2004;31:925-56.)

**Fig. 84.16** Posterior drawer test. The knee is placed in 90 degrees of flexion and the foot is stabilized with pressure toward the examination table. The proximal end of the tibia is then grasped and a posterior force applied to it. (From Brown JR, Trojan TH. Anterior and posterior cruciate ligament injuries. Prim Care 2004;31:925-56.)
posterior joint capsule. The most common mechanism of injury to this muscle is hyperextension of the knee. Posterior dislocation of the tibia during knee flexion may also injure this muscle.

Patients may describe sudden calf pain while running or making a sudden stop or cut. Pain and swelling of the calf develop over the next day, and tenderness is typically found at the musculotendinous junction of the medial (more common) or lateral head of the gastrocnemius muscle. Complete rupture of the head of the gastrocnemius muscle is associated with retraction of the muscle belly. Acute posterior compartment syndrome has been associated with rupture of the medial head of the gastrocnemius muscle.14

Plain radiographs are not indicated. MRI may be helpful if a soft tissue injury is in doubt. Acute strains of the gastrocnemius muscle are treated conservatively with ice, compression wraps, and antiinflammatory medications. Gentle passive and active stretching exercises are begun early.

**Strain or Rupture of the Plantaris Muscle**

The plantaris is a pencil-shaped muscle that originates at the lateral condyle of the femur and passes below the soleus to attach to the Achilles tendon. Strain of the proximal plantaris muscle may occur with an injury to the ACL.

Patients with plantaris muscle rupture may experience a deep, disabling pain in the calf followed by a dull, deep ache. On examination, tenderness is greatest just lateral to the midline of the posterior aspect of the calf. No diagnostic testing is indicated. Plantaris muscle strains and ruptures are treated conservatively.

**Shin Splints**

Shin splints are also known as the medial tibial stress syndrome, which is characterized by diffuse tenderness over the posteromedial aspect of the distal third of the tibia. It is believed to represent a peristalgia or tendinopathy along the tibial attachment of the tibialis posterior or soleus muscle. It may be confused with a stress fracture.

Common contributing factors are improper shoe wear, rapid transition in training, inadequate warm-up, running on uneven or hard surfaces, running in cold weather, and anatomic considerations. Patients with mild cases of shin splints have pain during exercise, whereas those with more severe cases have pain at rest.

Diagnostic tests are not indicated for shin splints unless a tibial stress fracture is a consideration. Treatment of shin splints involves relative rest, training adjustment, and antiinflammatory medications. Runners should be instructed to avoid running on hills and uneven surfaces.13

**OVERUSE INJURIES**

Common tendinopathies and bursitis of the knee are described in Chapter 86.

**OSGOOD-SCHLATTER DISEASE**

Osgood-Schlatter disease is an overuse injury that involves traction apophysitis at the tibial tubercle. It is often seen in adolescents during a growth spurt, when the apophysis in this region becomes weaker than the surrounding bony and tendinous tissues. The condition is bilateral in 20% to 30% of cases. Its cause is unknown.

Patients with Osgood-Schlatter disease complain of pain and swelling over the tibial tuberosity. They may describe worsening of the pain with jumping, squatting, or kneeling. The pain may be intermittent and is rarely severe enough to interrupt daily activity. Physical examination demonstrates localized pain and swelling over the tibial tuberosity.

A lateral knee radiograph is the most useful view and may show separation of the apophysis or fragmentation of
a portion of the tibial tubercle. The appearance of tibial tubercle fragmentation may represent a normal variant in ossification of the tibial tubercle. Radiographic findings without associated clinical symptoms should be interpreted with caution.

Osgood-Schlatter disease is generally a self-limited condition. In most cases, treatment is nonoperative and consists of modification of activity, nonsteroidal antiinflammatory drugs (NSAIDs), and physical therapy. The family of an adolescent with this disorder should be counseled that the symptoms may take up to 12 to 18 months to resolve.

**STRESS FRACTURES**

A stress fracture is a partial or complete bone fracture that results from repeated stress. Stress fractures are most common in the lower extremities (tibia, fibula, and metatarsal bones). They occur as a result of a repetitive use injury that exceeds the intrinsic ability of the bone to repair itself. Tibial stress fractures are commonly seen in military recruits, as well as in track and long-distance runners.

Patients have localized dull pain in the lower extremity that is not related to trauma. The pain typically worsens during exercise or weight bearing. Stress fractures can be manifested in a similar fashion as shin splints but are associated with more focal bony tenderness.

Evidence of a stress fracture may not appear on plain radiographs for up to 2 to 10 weeks after the onset of symptoms. The presence of a transverse fracture line across the entire anterior shaft of the tibia on a plain radiograph is considered a poor prognostic sign and is associated with a greater likelihood of nonunion. Radiouclide scintigraphy can confirm the diagnosis as early as 2 to 8 days after the onset of symptoms.

Initial treatment consists of conservative therapy: ice, antiinflammatory pain medication, and rest for several weeks or until the extremity is free of pain. Tibial fractures that do not improve with conservative management may require splinting in a walking boot or air splint. A midshaft tibial fracture is splinted until the extremity is pain free with radiographic evidence of healing.

**OTHER DISORDERS**

**OSTEOCHONDritis DISSEcANS**

Osteochondritis dissecans is a potentially reversible idiopathic lesion of subchondral bone. It is seen more often in children and adolescents. Osteochondritis dissecans of the knee occurs most commonly on the posterolateral aspect of the medial femoral condyle (70% to 80%) (Fig. 84.17). Inflammation, genetics, ischemia, ossification, and repetitive trauma have all been hypothesized as possible causes.

Most children and adolescents with this disorder have a stable lesion and nonspecific complaints, such as aches or activity-related knee pain localized to the anterior aspect of the knee. Both knees should be examined because the condition is bilateral in 20% to 25% of cases. Initial plain radiographs should include AP, lateral, and tunnel views of the knee.

Stable osteochondritis dissecans lesions have a favorable healing rate with conservative management alone (modified activity, NSAIDs, rehabilitative exercises). Patients and their parents should be instructed that it takes up to 12 to 18 months for healing to be complete.

**OSTEONECROSIS**

Osteonecrosis of the knee is usually idiopathic and is most commonly located on the medial femoral condyle. It may be associated with steroids, irradiation, and systemic diseases such as sickle cell anemia and rheumatologic disorders. Osteonecrosis occurs when the blood supply to the bone is disrupted, which results in bone infarction.

The patient has a sudden onset of pain over the anteromedial (most common) aspect of the knee. The pain may become worse at night or increase with activity. Idiopathic osteonecrosis is typically seen in women older than 60 years. The patient may have a joint effusion or decreased range of motion of the knee joint.

Radionuclide scintigraphy or CT may be required to detect the disease in its early stages. Plain radiographic findings in patients with early disease are usually normal. Patients with early stages of osteonecrosis are treated conservatively with partial weight bearing and antiinflammatory medications. Patients with advanced disease may require surgery to restore the articular surface. Total knee arthroplasty is reserved for disease that has expanded to the lateral compartment.

**PATELLOfEMORAL PAIN SYNDROME**

Patellofemoral pain syndrome refers to the clinical manifestation of anterior knee pain related to changes in the patellofemoral articulation. Patients are generally between the ages
of 10 and 20 years and usually have complaints of nonspecific anterior knee pain that is not related to trauma. Athletes may experience symptoms after periods of overactivity. Elderly patients may exhibit symptoms if they have arthritis that affects the patellofemoral joint. The most important risk factors are overuse, quadriceps weakness, and soft tissue tightness. In most cases the etiology is multifactorial.18

The patient has a history of mild to moderate anterior knee pain. The knee may be more painful with prolonged flexion, stair climbing, or kneeling. Physical examination may show a slight effusion, along with patellar crepitus on range of motion. Applying direct pressure to the anterior aspect of the patella may reproduce the patient’s pain.5

Plain radiographs are not indicated. CT or MRI can detect abnormalities in the articular surface of the patella. In most cases, a physical therapy program that strengthens the quadriceps muscle can successfully reduce the symptoms. Surgery is needed no further treatment.19

**POPLITEAL CYST**

A popliteal cyst, or Baker cyst, is an inflammation of the semimembranosus or medial gastrocnemius bursa. A Baker cyst is produced by herniation of the synovial membrane

through the posterior knee capsule. It is usually the result of synovitis, arthritis, or an internal derangement of the knee that results in excess synovial fluid in the bursa.

Intermittent swelling can develop behind the knee. If the bursa ruptures, the patient may complain of calf pain, and the findings may be similar to those in patients with thrombophlebitis.

Ultrasonography is helpful to distinguish Baker cysts from other disorders, such as popliteal artery aneurysms, neoplasms, and thrombophlebitis. Treatment is based on the underlying cause. Asymptomatic cysts found incidentally need no further treatment.19

**DOCUMENTATION**

The following issues should be clearly documented in a patient with knee or lower leg injury:

- History: Mechanism of injury; duration and location of symptoms; associated symptoms; exacerbating or alleviating factors; complaints of weakness, numbness, or instability; complicating medical factors; and previous interventions, imaging, or evaluations
- Physical examination: Neurovascular status (before and after splint placement or reduction), compartment assessment, skin integrity, stability assessment, and associated injuries
- Radiography: Anteroposterior or lateral films of the joint above and below the injury; prereduction and postreduction films indicated for most reductions
- Medical decision making: Any emergency reduction secondary to neurovascular compromise and reasons for emergency or nonemergency consultation or follow-up
- Procedures: Neurovascular status both before and after reduction or splint placement, skin integrity, and postreduction fracture alignment
- Patient instructions: Discussion with the patient regarding splint care, appropriate crutch use, importance of range-of-motion exercises, weight-bearing status, warning signs for neurovascular impairment and compartment syndromes, and arrangements for follow-up or return to the emergency department

**PATIENT TEACHING TIPS**

A patient in whom a strain, sprain or stable injury of the knee is diagnosed should be discharged home in a hinged brace (fully unlocked). If discharged in a knee immobilizer, the patient should be instructed to perform gentle range-of-motion exercises multiple times per day to prevent joint stiffness.

A patient with a tibia fracture who is sent home should be educated about compartment syndrome and told to return to the emergency department if either severe pain or numbness in the foot or leg develops within the first 48 hours.

A patient with an acute injury should be instructed to:
- Elevate the injured area above the level of the heart for the first 48 hours after the injury.
- Apply ice to the injured area while avoiding direct contact of ice with bare skin and getting the splint moist.

In a patient discharged from the emergency department on crutches:
- Crutch training should be given.
- The ability of the patient to safely use crutches should be observed before discharge.

Foot and Ankle Injuries

Jorge del Castillo

EPIDEMIOLOGY

Inversion injuries occur at a rate of 1 per 10,000 people per day, which equates to about 28,000 injuries per day in the United States. Injury to the dominant ankle is more likely than injury to the nondominant ankle. These injuries are common during recreational sports involving running, such as basketball, soccer, baseball, and volleyball.

Inversion injuries may at first glance appear to be common and minor. A large percentage of these injuries continue to be symptomatic for a year or longer after the injury. Chronic instability eventually develops in some individuals and requires surgical repair.1

PATHOPHYSIOLOGY

ANATOMY

The ankle is composed of two joints: the talar mortise and the subtalar joint. The talar joint is a modified hinge joint similar to a “mortise and tenon,” as referred to in carpentry. It is composed of three bones: the tibia, the mortise, and the talus of the fibula, which form the tenon (Fig. 85.1). The plafond or “ceiling” of this joint is formed by the tibia with its medial malleolus and articulation with the fibula.

The dome of the talus has a trapezoidal shape—wider anteriorly and narrower posteriorly. This anatomic shape confers greater stability in dorsiflexion. However, when the ankle moves into plantar flexion, the narrow part of the talus sits in the mortise, which results in ankle instability and predisposes it to injury.2,3

Ligaments of the Ankle

The medial side of the ankle is supported by the deltoid ligament (Fig. 85.2). The deltoid ligament has five components: one deep and four superficial. The deep ligament attaches to the tibia and the undersurface of the talus. The superficial ligaments are the tibionavicular, anterior talotibial, calcaneotibial, and posterior talotibial.

The lateral aspect of the ankle has three supporting ligaments: the anterior talofibular, calcaneofibular, and posterior talofibular (Fig. 85.3). The tibiofibular ligaments include the anterior and posterior inferior ligaments, which bind the distal ends of theibia and fibula, and the superior ligaments of the
same name, which bind the tibia and fibula at the proximal articulation. Other supporting structures are the inferior transverse ligament and the interosseous ligament. The latter is not part of the ankle but nevertheless provides a strong bond between the tibia and fibula.2,3

**PRESENTING SIGNS AND SYMPTOMS**

As noted previously, the ankle is a modified hinge joint; its motion is predominantly executed in a sagittal plane.

Most ankle sprains are due to inversion during plantar flexion of the ankle. Thus approximately 85% of injuries involve the lateral ligaments: the anterior talofibular ligament, the calcaneofibular ligament, and the posterior talofibular ligament. Of sprains caused by inversion, 65% are isolated to the anterior talofibular ligament. In some patients the subtalar complex may also be injured. The calcaneofibular ligament is rarely injured in isolation. Classification of these injuries and examination findings are presented in Table 85.1.

Isolated injury to the medial (deltoid) ligament is uncommon, and such injury is usually accompanied by a medial malleolar fracture. Distal tibiofibular syndesmotic rupture is very rare and is associated with forceful dorsiflexion and external rotation.2,4

**HISTORY AND PHYSICAL EXAMINATION**

A methodic approach to elicitation of the history of the injury and examination of the ankle joint is of paramount importance. Frequently, the mechanism is unknown because of the sudden and rapid occurrence of the injury. Specific questions about the mechanism, time of the injury, ability to bear weight, and previous history of injury involving the affected joint are helpful in arriving at an accurate diagnosis (Box 85.1).

The physical examination (Box 85.2) should be thorough and orderly with the intent of assessing joint stability and possible neurovascular compromise. The emergency physician (EP) should make sure that the patient is in a comfortable

position for the examination. Many times patients are examined in hallways while sitting in chairs with their feet resting on the floor or a wheelchair footrest. Uncomfortable approaches to examination of the ankle—or any joint for that matter—are detrimental to the welfare of both the patient and physician. All that is derived from this approach is an incomplete examination and an uncomfortable patient and physician.

The EP should make sure that the patient is seated at a level higher than the examiner (e.g., seated on a gurney with the affected limb dependent, seated on the examining table with both extremities on the table). Never begin the examination at the point of maximal swelling and tenderness. The examination should begin with visual inspection to assess the degree of swelling and the presence of any deformity and discoloration. The neurovascular status of the extremity is evaluated by testing sensation, capillary refilling, and presence of pulses. Once a preliminary assessment is done, the EP should proceed in detail from distal to proximal in an orderly fashion as noted in Box 85.2.5

OTHER MANEUVERS

Other maneuvers sometimes used in the evaluation of an injured ankle are worth mentioning. The anterior drawer test (Fig. 85.4) is used to determine the integrity of the anterior talofibular ligament. It is, unfortunately, not very reliable, especially in acute injuries with significant swelling and pain.

It is performed by holding the foot at the calcaneus with one hand while the other hand stabilizes the extremity at its middle third. The foot is moved forward while one observes or feels (or both) for displacement of the foot and ankle anteriorly.

The side-to-side test (clunk test) evaluates the integrity of the tibiofibular ligament. The foot is held in a neutral position and then moved from side to side. A “clunk” is heard or felt if the ligament is ruptured.

The talar tilt test can be used to assess the deltoid ligament and the calcaneofibular ligament by applying eversion and inversion stress, respectively. The calcaneus is held in one hand while the examiner moves the ankle into inversion or eversion (Fig. 85.5). Frequently, it is accompanied by simultaneous radiographic evaluation to determine the amount of tilt at the level of the talus.2

Stress testing is not generally performed in the acute phase of an injury because of its inaccuracy and the pain that it inflicts on the patient. Since the advent of magnetic resonance imaging (MRI), which can reveal soft tissue injuries of varying degrees, stress testing is rarely used at all.2

Differential Diagnosis and Medical Decision Making

Ankle sprains result from traumatic rotational forces applied to the ankle and usually occur in individuals who are involved in sports activities. They have been classified to better understand treatment modalities, as well as prognosis.
CLASSIFICATION OF ANKLE SPRAINS

Subluxation of the Peroneal Tendons

The peroneus longus and brevis tendons lie in a shallow groove immediately posterior to the distal end of the fibula. Rupture of the superior peroneal retinaculum results in subluxation or dislocation of the peroneal tendons. This injury is often mistaken for a common sprain in the emergency department (ED). However, it differs in that the pain and swelling are located along the posterior border of the lateral malleolus. It results from forced dorsiflexion with reflex contraction of the peroneal muscles. Patients complain of pain and a snapping sensation over the posterolateral aspect of the ankle with weakness of eversion.6

During physical examination, pain is elicited on palpation of the area, and swelling is also noted. The subluxation can be reproduced with dorsiflexion and eversion of the foot.

Do not mistake subluxation of the peroneal tendons for an ankle sprain because the treatment and prognosis are different.

Treatment is directed at stabilization of the subluxed tendon. A U-shaped felt pad is placed over the lateral aspect of the ankle with the tip of the fibula lying inside the “U.” The ankle is then taped to ensure that the U-shaped pad stays in place. Refer to an orthopedic surgeon for further evaluation in the event that corrective surgery is warranted.

Achilles Tendon Injuries

The most common conditions affecting the Achilles tendon in patients seen in the ED range from tendonitis to rupture. Rupture of the Achilles tendon is missed in more than 20% of patients with this injury. The rupture may be partial or complete. Occasionally, because of significant swelling and a hematoma over the area, a discernible defect in the tendon may be difficult to identify.

The history usually includes some form of violent motion around the ankle; the injury is often seen in basketball and tennis players. Weekend athletes in their third or fourth decade are most commonly affected.

Physical examination reveals swelling and tenderness, as well as a partial or complete defect in the tendon. A positive Thompson test is diagnostic. It is performed by having the patient lie prone on a gurney or stand with the knee of the affected leg resting on a chair (Fig. 85.6). The examiner then squeezes the calf muscles. Individuals with normal Achilles tendons will plantar flex as the maneuver is performed.3

Note that the Thompson test can be misleading, especially with partial tears, because the accessory ankle flexors are often squeezed together with the contents of the superficial leg compartment.

Treatment consists of either a compression wrap or a short leg plaster splint with the foot positioned in equinus (plantar flexion). Crutches, non-weight bearing, and analgesics are also indicated. Prompt orthopedic consultation to determine the necessity for surgical repair is advised.

CLASSIFICATION OF FRACTURES

Several classifications of ankle fractures have been published over the years in an effort to facilitate accurate description and subsequent treatment. The most comprehensive classification, still in use, was proposed by Lauge-Hansen in 1950 and was based on cadaver experiments involving the use of foot position (supination or pronation) and direction of the force exerted on the joint (external rotation, adduction, or abduction) at the time of the injury. The Danis-Weber Arbeitsgemeinschaft für Osteosynthesefragen (AO) classification proposes a simpler description based on the location and appearance of the fibular fracture. The fracture lines are designated A, below the syndesmosis; B, at the level of the syndesmosis; and C, above the syndesmosis (Fig. 85.7).

The Orthopedic Trauma Association has since expanded the Danis-Weber classification by keeping the three types (A, B, and C) and adding nine groups (1, 2, and 3 for each type) and 27 subgroups.3

In 1987, Tile recommended another classification that identifies ankle fractures by their stability. Because unstable fractures require a different treatment approach than stable fractures do, such distinction is clinically important. For example, identification of a medial injury will generally determine the stability of the ankle joint. Therefore, always suspect an unstable fracture of the ankle when the medial structures are identified as injured clinically or radiographically.5,7

Danis-Weber Classification System

This classification system has four injury patterns: (1) supination adduction (SA or Weber A), (2) supination external rotation (SE or Weber B), (3) pronation abduction (PA or Weber...
CHAPTER 85  FOOT AND ANKLE INJURIES

PRONATION EXTERNAL ROTATION (PE, WEBER C2) In pronation external rotation, pronation (eversion) of the foot and application of an external rotation force through the talus result in up to four sequential injuries (Fig. 85.11). The first two injuries are the same: transverse fracture of the medial malleolus (PE I), followed by a tear of the anterior inferior tibiofibular ligament (PE II). The third injury is a short spiral or oblique fracture, usually 6 to 8 cm above the syndesmosis but possibly as high as the midshaft level (PE III). The fourth injury is fracture of the posterior malleolus (PE IV).

Maisonneuve Fracture (Webber C3) The exact mechanism leading to a Maisonneuve fracture is not clear. It appears to combine different forces and possibly shifting foot positions. Patients have isolated medial ankle tenderness and swelling. On further examination, tenderness at the level of the proximal end of the fibula is also identified. This fracture is unstable and warrants clinical and radiographic evaluation of the entire lower extremity below the
knee. It often goes unrecognized and is identified merely as “just another ankle sprain.” Therefore, vigilance must be exercised when a medial ankle injury is identified in any patient. These medial ankle injuries could be limited to the deltoid ligament, an isolated fracture of the posterior tibial tubercle, or a medial malleolar fracture in the absence of a lateral malleolar fracture. The classic appearance of the injury is a fracture of the neck of the fibula—either linear or comminuted (Fig. 85.12). Emergency orthopedic consultation is necessary.4

Salter-Harris Classification System

The Salter-Harris classification system describes injuries that occur only around growth plates. Hence, just children have Salter-Harris fractures.

Injuries to the ankle in the pediatric population generally occur at the level of the bone physis. The Salter-Harris classification system enables definition of the type and severity of the fracture. Salter-Harris fractures are generally broken down into five categories as shown in Figure 85.13 and Table 85.2.5

Triplane Fractures

This type of fracture is generally seen in older children with partially closed epiphyses and resembles a Salter-Harris type IV fracture. The mechanism is usually external rotation. Even with proper care and reduction, this fracture can result in epiphyseal growth arrest and deformity. If unsure of the fracture lines on plain film radiographs, computed tomography (CT) is recommended to ascertain the position of the fracture fragments (Fig. 85.14).

DISLOCATIONS

Dislocations can occur at multiple sites in the foot and ankle. An in-depth description of these dislocations is beyond the scope of this chapter. Nevertheless, two of these types of dislocations are worth mentioning.

Dislocations at the level of the tibiotalar joint, or tibial dislocations, are generally associated with fractures. On occasion, a pure tibial dislocation will occur. They require prompt anatomic reduction in an effort to diminish cutaneous and neurovascular injury. If orthopedic consultation is not readily available, reduction under conscious sedation should be performed by the EP.

URIES

Fracture

Triplane fracture.

Most heights.6

ball), as well as from motor vehicle accidents and falls from

heights or motor vehicle accidents. These injuries

may occur at the neck or the body of the talus. Avascular

talocalcaneal and talonavicular joints. Subtalar

fractures result from a mechanism similar to that of

ankle sprains. When the ankle is forcibly inverted while in

plantar flexion or dorsiflexion, the dome of the talus is com-

pressed against the fibula or the tibial plafond. This results in

several degrees or “stages” of lesions (Fig. 85.15). More often

than not, the initial radiographs are negative, and diagnosis

will require CT or MRI. The diagnosis is missed in 40% to

50% of patients seen in the ED with an ankle injury. There-

fore, a high index of suspicion is warranted with these inju-

ries, especially if the patient has experienced reinjury, chronic

swelling, or locking of the ankle 4 to 5 weeks after the injury.7

Fig. 85.14 Triplane fracture.

The second type is subtalar dislocation. This injury occurs

at the level of the talocalcaneal and talonavicular joints. Sub-
talar dislocations can be medial or lateral, depending on

the direction of the foot and the effecting forces. These high-

energy injuries result from sports (basketball and base-

ball), as well as from motor vehicle accidents and falls from

heights.4

Clinical examination of patients with subtalar dislocations

shows significant and obvious deformity. Skin tenting and

neurovascular compromise should be promptly assessed and

remediated by reduction. Standard lateral radiographs are

sometimes not diagnostic, and an AP projection of the foot

may be the only view that depicts the actual talonavicular
dislocation. CT is recommended to further assess for associ-

ated fractures and the integrity of the reduction. Open subtal-
dislocations carry significant morbidity and require emer-
gency orthopedic intervention.

FOOT INJURIES

Talar Fractures

Injuries to the talus result from high-energy trauma such as

falls from heights or motor vehicle accidents. These injuries

may occur at the neck or the body of the talus. Avascular

necrosis is common when the injury involves the neck of the

talus because of the limited blood supply to this area of the

bone. Most of these injuries are significant and all warrant

orthopedic consultation. For complete classification details,

see Fracture and dislocation compendium. Orthopaedic

Trauma Association Committee for Coding and Classifica-

Osteochondritis Dissecans (Osteochondral Fracture)

These fractures result from a mechanism similar to that of

ankle sprains. When the ankle is forcibly inverted while in

plantar flexion or dorsiflexion, the dome of the talus is com-

pressed against the fibula or the tibial plafond. This results in

several degrees or “stages” of lesions (Fig. 85.15). More often

than not, the initial radiographs are negative, and diagnosis

will require CT or MRI. The diagnosis is missed in 40% to

50% of patients seen in the ED with an ankle injury. There-

fore, a high index of suspicion is warranted with these inju-

ries, especially if the patient has experienced reinjury, chronic

swelling, or locking of the ankle 4 to 5 weeks after the injury.7

Table 85.2 Salter-Harris Classification of Fractures

<table>
<thead>
<tr>
<th>TYPE</th>
<th>DESCRIPTION</th>
<th>RADIOGRAPHIC FINDINGS</th>
<th>TREATMENT</th>
</tr>
</thead>
<tbody>
<tr>
<td>I</td>
<td>Separation of the two portions of bone, with the growth plate being the area of weakest link</td>
<td>No changes seen on radiographs, although the growth plate may look wider than that in the other limb</td>
<td>Immobilization for a short period</td>
</tr>
<tr>
<td>II</td>
<td>Most common fracture; occurs partially through the growth plate, with the rest of the fracture extending back into the shaft of the bone; that fragment of bone is known as the Thurston-Holland sign</td>
<td>Separation of the physis and metaphyseal fragment with varying degrees of displacement</td>
<td>Immobilization in a short leg splint or cast and orthopedic follow-up</td>
</tr>
<tr>
<td>III</td>
<td>Fracture occurring partially across the growth plate and then extending out through the epiphysis and into the joint space</td>
<td>The fracture fragment is epiphyseal, with varying degrees of displacement</td>
<td>Because these fractures may affect the joint, the prognosis is more guarded; immobilization as described previously for type II fractures and orthopedic follow-up</td>
</tr>
<tr>
<td>IV</td>
<td>Fracture extending from the metaphysis, across the growth plate, and into the joint through the epiphysis; premature arrest of normal growth is common</td>
<td>Combination of types II and III, with varying degrees of displacement</td>
<td>Immobilization and prompt orthopedic follow-up; surgical repair usually needed to restore proper anatomic alignment</td>
</tr>
<tr>
<td>V</td>
<td>Fracture involving compression of the growth plate; the prognosis is variable, with premature arrest of normal growth being the biggest risk</td>
<td>Radiography is generally of little help in diagnosing this fracture; however, obliteration of the physis is an indication of severity</td>
<td>Immobilization and emergency orthopedic consultation; surgical repair usually needed to restore proper anatomic alignment</td>

</table>
Calcaneal Injuries

The calcaneus is the most frequently fractured tarsal bone and accounts for more than 60% of tarsal fractures. These fractures are frequently work-related injuries in roofers or other individuals working at heights. The majority are intraarticular, with the remainder being classified as extraarticular.

The most common extraarticular fracture is a calcaneal body fracture. In decreasing frequency, other locations of calcaneal fractures are at the anterior process, the superior tuberosity, and the area of the sustentaculum tali; isolated injuries are rarely seen at these sites. Calcaneal fractures are infrequently encountered as open fractures. Open injuries are reported to occur in only 2% of cases. As a result of the accompanying mechanisms and forces related to calcaneal fractures, other pathology such as spinal injuries and extremity fractures are usually associated with injuries to the os calcis. Multiple complications such as gait abnormalities, arthritis, and leg length discrepancy are generally the sequelae of calcaneal fractures.8

Plain films, including AP, lateral, and axial views of the hindfoot, provide a good initial assessment. CT is generally used to ascertain the true extent of these complex fractures.

One method of assessing the integrity of the calcaneus is measurement of the Böhler angle. This angle is normally 30 to 35 degrees and is determined by tracing two lines on a radiograph of the foot (Fig. 85.16). One line is drawn from the posterior tuberosity to the apex of the posterior facet. A second line connects the apex of the posterior facet to the anterior (beak) process. An angle of 20 degrees or less should raise suspicion for a compression fracture of the calcaneus.3

Another less frequently used angle measurement is the crucial angle of Gissane. This angle is formed by the downward portion of the posterior facet where it connects to the upward portion. This angle normally measures 100 degrees.3

Other Tarsal Conditions

Avascular necrosis occurs in many areas of the skeleton. The foot is not spared, with the tarsal navicular experiencing the greatest frequency of this condition. Stress fractures can result in avascular necrosis when they go unrecognized and untreated.8 Examples of these injuries, with a description of the clinical findings, diagnosis, and treatment, appear in Table 85.3.

Lisfranc Injury

A Lisfranc injury is uncommon and generally associated with significant force. Physical examination reveals significant swelling and tenderness of the midfoot area commensurate with the magnitude of the injury. On occasion, ecchymoses of the midarch area of the foot are present and are diagnostic of this injury. The vasculature should be scrutinized carefully, especially if the intercommunicating arterial branch between the dorsalis pedis artery and the plantar arterial arch has been disrupted. It can lead to a compartment syndrome, which requires prompt intervention by an orthopedic surgeon.8

</table>
Metatarsal Fractures

Three types of fractures commonly occur in the proximal fifth metatarsal (proximal to distal): tuberosity avulsion fracture, Jones fracture, and proximal diaphyseal stress fracture. Each has distinct characteristics, and the approach to treatment is often controversial. Nevertheless, most of these fractures heal with immobilization over a period of 3 to 8 weeks, depending on location. Treatment of displaced intraarticular fractures, delayed union, and nonunion usually requires operative methods. A Jones fracture has a high rate of nonunion and may require surgical intervention. Patients must be warned of this potential problem. Tuberosity fractures and Jones fractures must not be confused despite their proximity on the fifth metatarsal (Fig. 85.17).#3

Freiberg Disease

Freiberg disease is caused by repetitive trauma to the head of the second metatarsal, which deprives the epiphysis of adequate circulation, with consequent necrosis of the metatarsal head and pain in the area of the second metatarsal in the forefoot. Radiography shows flattening of the metatarsal head with a fragmented epiphysis.

Freiberg disease is most common in adolescent girls and is associated with the wearing of high-heeled shoes.

Treatment is directed at prevention of trauma by rest and diminishing sports activities, as well as by wearing flat shoes instead of high heels. Nonsteroidal antiinflammatory drugs (NSAIDs) may be used as necessary to decrease inflammation.#10

Sesamoid Bone Fractures

The foot has many sesamoid bones. However, those most commonly injured are in the area of the great toe and occasionally in the os trigonum located posterior to the posterior tubercle of the talus. These fractures are infrequent and often go unrecognized. They can occur as a result of direct and indirect trauma. Direct traumatic injuries result from crush-type mechanisms such as falling from a height or direct impact with an external object. Indirectly, the great toe suffers a hyperdorsiflexion-type injury that results in the fracture. In the case of the os trigonum, plantar flexion is the mechanism. Ballet dancers suffering from these injuries may at some time require removal of the bone because of chronic pain.#3

Examination reveals localized tenderness over the sesamoid and reproducible pain on dorsiflexion of the great toe. In the case of the os trigonum, physical examination almost always reveals tenderness anterior to the Achilles tendon and posterior to the tibia, as well as decreased plantar flexion. Pain is reproduced by plantar flexion or resisted plantar flexion of the great toe.

Radiographically, sesamoid fractures appear to have irregular margins, as opposed to the smooth contours of a bipartite sesamoid bone. Nonunion is frequent because of their poor vascular supply. This can result in chronic pain and swelling, as well as disability. It is therefore important to stress the need for orthopedic follow-up.

Treatment is directed at protection and immobilization of the affected area in either a walking cast or boot for 4 to 6 weeks.#3

Toe Fractures

Toe fractures are generally the result of direct trauma such as a heavy object falling on the foot. Occasionally, walking or kicking an immobile object will result in a displaced fracture. The eponym “nightwalker” fractures has been given to injuries that occur at night while navigating in a dark room.

Treatment is directed at anatomic integrity and immobilization. Therefore, reduction of displaced fractures with “buddy tape” immobilization is the standard. All other fractures that are not displaced warrant immobilization in the same fashion; a hard-soled cast shoe is recommended until the pain resolves, at which time an athletic shoe can be worn. In the event of a large intraarticular fracture fragment or significant displacement of the fragments, emergency orthopedic consultation is required.#8

Plantar Fasciitis

Plantar fasciitis is a fairly common condition in runners and long-distance walkers. It can have an acute cause from sudden excessive loading of the foot; more commonly, however, it becomes symptomatic in a gradual manner from excessive pronation of the foot. These chronic insults result in microtears of the plantar fascia.

Individuals with a high-arched foot are more prone to this injury. The patient reports pain in the plantar area of the foot, especially in the morning. Occasionally, the pain can be sharp and lancinating and resemble neuropathic pain.

Physical examination reveals tenderness along the plantar area of the hindfoot, near the origin of the plantar fascia. Swelling may be noted occasionally, as well as reproduction of the pain with dorsiflexion of the foot.

Treatment consists of ice massage and gentle stretching of the fascia. The latter is accomplished by stretching of the Achilles tendon, as well by rolling the foot back and forth over an object such as a can of soup. An orthotic device is helpful for individuals with excessive pronation on ambulation. Physical therapy in the form of massage and ultrasonography is sometimes necessary. Steroid injections can occasionally be used but should be done judiciously.#7

Tarsal Tunnel Syndrome

Compression of the posterior tibial nerve as it courses through the tarsal tunnel is known as tarsal tunnel syndrome. The tarsal canal is covered by the flexor retinaculum, which extends posteriorly and distally to the medial malleolus. The
floor is formed by the calcaneus, tibia, and talus. Tendons of
the flexor hallucis longus, flexor digitorum longus, and tibialis
posterior muscles, the posterior tibial nerve, and the posterior
tibial artery and vein pass through the tarsal tunnel.

Patients complain of shooting or radiating pain to the fore-
foot or the plantar arch. Numbness or a burning or tingling
sensation may also be present in the ankle, heel, arch, or toes.
Activity will often aggravate the symptoms.

Shooting pain distally may be elicited when the entrapped
nerve is percussed (Tinel sign). Nerve conduction velocity
studies are helpful in obtaining a definitive diagnosis.
The multiple causes of tarsal tunnel syndrome are listed in
Box 85.3.

Several treatment options are available, depending on the
cause. Conservatively, the area can be put at rest with the use
of night splints. Orthotics can be used to correct hyperprona-
tion of the foot. Women should stop wearing high-heeled
shoes.

NSAIDs and occasionally physical therapy may be of
benefit. Steroid injections may also be of some help. Ulti-
mately, tarsal tunnel release can be performed to alleviate the
condition.

**DIAGNOSTIC TESTING**

**IMAGING**

Views of the ankle should include AP, lateral, and mortise
views. The mortise view allows a fairly good image of both
the mortise and the talar dome.

Stress views are sometimes helpful but are not presently
used as much as in the past. A posteroanterior or mortise view
is obtained while stressing the affected ligaments (lateral liga-
ments) to ascertain the degree of instability as identified by
talar tilt. Comparison with the uninjured ankle is necessary,
and joint stability is defined as less than 5 degrees of differ-
ence between the injured and uninjured sides. A tilt angle
greater than 15 degrees with respect to the uninjured side
often signifies rupture of the anterior talofibular and calcaneo-
fibular ligaments.3

Another radiographic method of assessing ankle joint sta-
bility is identification of the medial clear space. This is the
distance, as measured on a mortise view, between the lateral
border of the medial malleolus and the medial border of the
talus. Any value greater than 4 mm is considered abnormal
and is a sign of instability (Fig. 85.18).3

Finally, CT and MRI have become very popular in the
diagnosis of these injuries but are still not in common use in
the ED.

**Ottawa Ankle Rules**

In an effort to decrease the number of ankle radiographs used
in the diagnosis of acute ankle injuries, Stiell et al. from the
Ottawa Civic and the Ottawa General Hospitals in Canada
conducted a prospective study that included more than 750
patients seen in the ED with acute blunt ankle injuries. They
determined that ankle films were necessary only when patients
with pain near the malleoli exhibited one or more of the find-
ings shown in Box 85.4.

Likewise, for injuries to the foot, radiographs would be
necessary only with pain in the midfoot area and bone
tenderness at the navicular, the cuboid, or the base of the fifth
metatarsal.11
**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

The patient can begin exercises when the pain subsides (do not use heat) and can return to full activity when full pain-free motion and equal strength are attained in both ankles.

For weekend and other athletes, depending on age and conditioning, **Box 85.6** outlines some guidelines when sports activities can be resumed safely.

---

**BOX 85.5 ICEMM Mnemonic for Treatment of Fractures of the Foot and Ankle**

ICE: Every 2 hours or as needed for the first 24 to 48 hours

**COMPRESSION:** Compression dressing (Webril or Ace) to decrease swelling; ankle stirrup to lend stability, if indicated

**ELEVATION:** To reduce swelling

**MOBILIZATION:** Early, as soon as patient is pain free

**MEDICATION:** Nonsteroidal antiinflammatory drugs or narcotics when applicable

**BOX 85.6 Guidelines for When Sports Activities Can Be Resumed Safely**

Type I injury (ligament stretch or minor tear): Return to play in 1 to 10 days

Type II injury (partial ligament tear): Return to play in 2 to 4 weeks

Type III injury (complete ligament tear): Return to play in 5 to 8 weeks

REFERENCES

experienced acutely, although tendinitis is no longer thought to be an inflammatory disorder. Bursae may become inflamed for many reasons: chronic friction, trauma, crystal deposition, infection, and systemic diseases (rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, tuberculosis, and gout). Because tendons frequently cross over bursae, it is not uncommon for bursitis to be secondary to overlying tendonitis (e.g., supraspinatus tendinitis, subacromial bursitis).

TENDONITIS

The signs and symptoms of tendinitis can be quite variable. Pain is the most common complaint of patients with joint problems seen in the ED. Particular attention should be paid to the location of the pain; it can be articular (within the joint capsule), as in septic arthritis, or periarticular (outside the joint capsule), as in tendinitis or bursitis (Table 86.1).

BURSITIS

Inflammation of a bursa may be infectious or traumatic, degenerative, or due to underlying systemic disease. Risk factors for the development of bursitis are acute trauma, repetitive injury to the painful area, infections, tuberculosis, gout, pseudogout, uremia, and rheumatoid arthritis. The diagnosis is made clinically based on tenderness at a bursal site, swelling of a superficial bursa, and localized pain with motion and at rest. Regional loss of active motion may occur as a result of swelling; however, range of motion should not be affected in patients with aseptic bursitis (see the Red Flags box on tendinopathy and bursitis).

KEY POINTS

- Emergency department treatment of tendinopathy and aseptic bursitis should be initiated conservatively with rest, immobilization of the involved tendon, compression of superficial bursae, and oral analgesia.
- Nonsteroidal antiinflammatory drugs may be useful in providing pain relief for patients with tendinopathy and bursitis but are no longer preferred over other analgesic regimens.
- Other emergency medical conditions such as septic arthritis, suppurative tenosynovitis, septic bursitis, fractures, and rheumatologic conditions should be excluded in the differential diagnosis.

PERSPECTIVE

Tendinopathy and bursitis are two of the most common joint complaints affecting adults seen in the emergency department (ED). Tendinopathy refers to pain, swelling, microscopic tearing, or degeneration of a tendon at its bony insertion. Bursitis refers to pain, swelling, or inflammation of the fluid-filled sac covering a joint. Both may be caused by overuse injuries or arthritis or may be symptoms of underlying systemic disease.

EPIDEMIOLOGY

The incidence of tendinitis increases with age as muscles and tendons lose some of their elasticity, and it is highest in the age group 25 to 54 years. Bursitis affects approximately 1 in 31 (3.2%) or 8.7 million people in the United States. According to the Centers for Disease Control and Prevention, in 2001 tendinitis was responsible for a median of 10 days away from work as compared with 6 days for all cases of nonfatal injury and illness. Most cases of tendinitis involved white, non-Hispanic women whose occupations had a highly repetitive component.

PATHOPHYSIOLOGY

Most often, tendon injury is caused by chronic overuse resulting in degenerative changes. The classic inflammatory signs of pain, warmth, erythema, and swelling may sometimes be experienced acutely, although tendinitis is no longer thought to be an inflammatory disorder. Bursae may become inflamed for many reasons: chronic friction, trauma, crystal deposition, infection, and systemic diseases (rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, tuberculosis, and gout). Because tendons frequently cross over bursae, it is not uncommon for bursitis to be secondary to overlying tendonitis (e.g., supraspinatus tendinitis, subacromial bursitis).

TENDONITIS

The signs and symptoms of tendinitis can be quite variable. Pain is the most common complaint of patients with joint problems seen in the ED. Particular attention should be paid to the location of the pain; it can be articular (within the joint capsule), as in septic arthritis, or periarticular (outside the joint capsule), as in tendinitis or bursitis (Table 86.1).

BURSITIS

Inflammation of a bursa may be infectious or traumatic, degenerative, or due to underlying systemic disease. Risk factors for the development of bursitis are acute trauma, repetitive injury to the painful area, infections, tuberculosis, gout, pseudogout, uremia, and rheumatoid arthritis. The diagnosis is made clinically based on tenderness at a bursal site, swelling of a superficial bursa, and localized pain with motion and at rest. Regional loss of active motion may occur as a result of swelling; however, range of motion should not be affected in patients with aseptic bursitis (see the Red Flags box on tendinopathy and bursitis).
CHAPTER 86  TENDINITIS AND BURSITIS

PRESENTING SIGNS AND SYMPTOMS

SHOULDER

Supraspinatus Tendinitis/Impingement Syndrome

Because of its complex structure and extensive range of motion, the shoulder is a joint predisposed to overuse injuries. The muscles of the rotator cuff (supraspinatus, infraspinatus, teres minor, subscapularis) and the glenohumeral ligaments serve to stabilize the joint. Impingement of these tendons occurs because of their position between the humeral head and acromion, which predisposes to chronic tendinosis6-7 (Table 86.2). Impingement syndrome is the number one cause of shoulder pain. It occurs in three progressive stages that worsen over time. Testing and staging of impingement syndrome are reviewed in Table 86.3.

In addition to the classic tests for impingement, the examiner should isolate and test individual muscles of the rotator cuff. The empty beer can position tests the supraspinatus by applying downward resistance to an arm in 90 degrees of abduction and 30 degrees of flexion with the thumb pointed downward. Applying resistance to external rotation when the elbow is against the patient’s body and bent at 90 degrees tests the infraspinatus and teres minor. The subscapularis is tested with the arm in the same position and applying resistance to internal rotation.

Subacromial Bursitis

The subacromial bursa lies under the acromion and coracoacromial ligament, to which it is attached. This bursa separates the ligament from the supraspinatus muscle and rotator cuff. Subacromial bursitis is thus thought to be an extension of supraspinatus tendinitis and typically follows this disorder’s stages of impingement. Pain and tenderness are localized to the lateral aspect of the shoulder, and signs of impingement are noted on physical examination (see Table 86.3).

ELBOW

Lateral and Medial Epicondylitis

The lateral and medial epicondyles are commonly injured as a result of repetitive use (Table 86.4). Pain often begins as a dull ache that increases with the inciting activity. Approximately 50% of tennis players will experience lateral
epicondylitis, although less than 5% of those with the syndrome play tennis. Radiographs may be helpful in atypical or prolonged cases to exclude rare pathologic conditions such as tumors.5

**Olecranon Bursitis**

Because of its superficial location at the posterior tip of the elbow, the olecranon bursa is vulnerable to injury. When traumatized, the resulting bursal hematoma causes pain and swelling mimicking acute bursitis. Infection is frequent and most often occurs locally as a result of puncture wounds or lacerations. If fever is present, septic bursitis must be considered and septic arthritis excluded.

**WRIST AND HAND**

The wrist and hand are composed of several tendons that pass through thick, fibrous retinacular tunnels. Overuse syndromes are thought to result from degenerative changes in the synovial lining between these tendons and the retinaculum (Table 86.5).

The differential diagnosis of wrist and hand tendinopathy also includes osteoarthritis of the carpometacarpal joint, rheumatoid or psoriatic arthritis of the flexor or extensor tendons, gonococcal tenosynovitis, and suppurative tenosynovitis. It is therefore important to review the clinical history for trauma, systemic symptoms, fever, penile or vaginal discharge, or rash (see the Red Flags box on suppurative tenosynovitis).

**HIP**

**Trochanteric Bursitis**

Patients with trochanteric bursitis are generally middle-aged or older women who complain of acute or chronic pain over the bursal area and lateral aspect of the thigh. The pain is increased when lying on the hip or walking down or climbing stairs and is classically worse at night. The pain associated with superficial bursitis can be reproduced by adduction and that of deep trochanteric bursitis by abduction. Approximately 50% of patients have pain with sequential flexion, abduction, external rotation, and extension of the hip while the contralateral knee is held in flexion (Patrick-Fabere test). Internal rotation does not usually provoke symptoms. The hip joint itself appears normal on examination, and no pain is elicited with flexion or extension.

**RED FLAGS**

**Suppurative Tenosynovitis**

Infection of the closed synovial sheaths of the flexors (rarely extensors), often of the fingers and hand

- Usually caused by trauma, with the type of bacteria depending on the traumatic exposure (bite wound, puncture, skin flora)
- Kanavel signs: tenderness over the flexor sheath, symmetric swelling of the digit, slightly flexed finger at rest, pain with passive extension of the finger
- Additional signs: local erythema, edema, lymphangitic streaking, fever, leukocytosis
- Treatment with broad-spectrum antibiotics, admission to the hospital, emergency surgical evaluation for incision and drainage
- Prophylaxis of all bite wounds recommended to prevent flexor tenosynovitis
These two disorders are grouped together because of their common anatomic location. The biceps femoris (hamstring) is a large muscle that inserts on the proximal end of the fibula. The popliteal muscle inserts on the lateral aspect of the distal end of the femur. Both tendons cross the knee joint and are subject to acute and overuse injuries, especially in athletes. In acute injuries, radiography should be performed to exclude an avulsion fracture. The diagnosis is made clinically. Patients report that the symptoms occur while running or playing sports. Tenderness to palpation at the insertions of these muscles is noted. Knee tendinopathies are treated conservatively with rest, ice, and referral for physical therapy. Surgery is rarely indicated.

**Prepatellar Bursitis**

Prepatellar bursitis (housemaid’s knee, nun’s knee) causes visual swelling over the lower pole of the patella. Range of motion may increase the pain as the bursa is placed under tension. Findings on examination of the joint are usually normal. Pyogenic prepatellar bursitis is an infection of this bursa and is common in children. This condition requires aspiration, immobilization, and antibiotic coverage. If acute episodes are not resolved within 2 days, incision and drainage should be considered.9
**Infrapatellar Bursitis**

The infrapatellar bursa is divided into two parts. Between the patellar ligament and the superior anterior surface of the tibia lies the deep part. The superficial aspect lies between the skin and patellar ligament. Deep infrapatellar bursitis is associated with tenderness on both sides of the tendon that increases with extreme flexion.10

If signs of infection such as loss of full extension of the knee or resistance to full flexion are present, aspiration of the infrapatellar bursa should be performed along with antibiotic therapy. If infection exists, evaluation for surrounding osteomyelitis is advisable.

**Anserine Bursitis**

Anserine bursitis most commonly occurs in obese older women with osteoarthritis and in endurance athletes. Pain characteristically occurs in the medial knee region over the proximal end of the tibia, increases on climbing stairs and with extremes of range of motion, and can radiate to the inner part of the thigh and midcalf region. The area of tenderness is localized to the medial aspect of the knee 2 inches below the joint margin, where the medial hamstrings (sartorius, gracilis, and semitendinosus) attach. The area is usually neither swollen nor warm.

**ANKLE**

**Achilles Tendinitis**

The Achilles tendon can be injured as a result of direct trauma, overuse, and medications such as steroids or fluoroquinolones11 (Table 86.6; also see the Red Flags box on fluoroquinolones and tendinopathy). It can also become inflamed as part of a systemic disease (ankylosing spondylitis, Reiter syndrome, gout, pseudogout). However, most causes of Achilles tendinitis are thought to be multifactorial. Additionally, the vascular supply creates a watershed area approximately 2 to 6 cm above the calcaneal insertion and is thought to be responsible for the clinical symptoms and pathologic disruption at this site. Tendon rupture must be ruled out. Diagnosis and treatment of Achilles tendon rupture are discussed further in Chapter 85.

</tbody>
</table>
If multiple joints are involved and the swelling is symmetric, viral infection, drug-induced reaction, and osteoarthritis should be considered. If the joint swelling is asymmetric, rheumatoid arthritis, lupus, and serum sickness should be considered. If a characteristic rash is present, rheumatologic diseases, Reiter syndrome, Lyme disease, and dermatomyositis should be considered. If the pain is migratory, one should consider gonococcal disease and rubella. If the pain occurred after trauma and a joint effusion is present, hemorrhathrosis is a possibility. If an audible “pop” is heard, tendon rupture should be considered. If no joint effusion is present, one should look for radiographic evidence of fracture.

**DIAGNOSTIC TESTING**

Patients with bursitis who have local signs of inflammation or any systemic symptoms should be evaluated for septic bursitis (see the Red Flags box on septic bursitis). Some distinguishing characteristics of septic bursitis are rapid onset, marked warmth, erythema, and extremely tense and painful bursae. The most commonly infected bursae are those most superficial: the olecranon and the prepatellar and superficial infrapatellar bursae. Bursae are most often directly inoculated with *Staphylococcus aureus* as a result of subcutaneous trauma.

**Septic Bursitis**

Erythema, edema, pain, or adjacent cellulitis over a bursa is a possible indication of septic bursitis. Patients with septic bursitis may have fever, leukocytosis, an elevated erythrocyte sedimentation rate, or neutrophilic bandemia, although systemic findings are not universal and are more common with deep bursa infection. Joint mobility may be preserved if no direct joint involvement is present. Any swollen bursa with signs of infection should be aspirated and sent for culture and Gram stain. Eighty percent of cases of bacterial septic bursitis are due to *Staphylococcus aureus*; the rest are due mostly to β-hemolytic streptococci. Antibiotic coverage should cover staphylococcal and streptococcal species, preferably guided by Gram stain results. Empiric choices for outpatients include dicloxacillin and clindamycin (with or without trimethoprim-sulfamethoxazole for patients at risk for methicillin-resistant *S. aureus*). Empiric intravenous antibiotic choices include cefazolin or vancomycin. The duration of therapy is between 1 and 4 weeks, depending on culture results and response to treatment. Any patient with severe inflammation, systemic signs, diabetes, or immunosuppression should be admitted for intravenous antibiotics and consultation with orthopedics for incision and drainage.

**IMAGING STUDIES**

A diagnosis of tendinitis or bursitis is generally made on clinical grounds, but radiologic studies are sometimes required to confirm the diagnosis by ruling out other causes of pain. Plain radiographs help distinguish extraarticular from articular sources of pain. In acute injury, radiographs are essential to exclude an avulsion fracture. Ultrasonography is useful in the evaluation of joint effusions and lesions involving tendons, ligaments, and skeletal muscles. It can be very helpful in guiding difficult joint aspirations in the ED and is particularly useful in imaging of the shoulder region. Ultrasound has been shown to be more sensitive than magnetic resonance imaging and is now considered the “gold standard” for evaluating tendon involvement with concomitant trauma or rheumatic diseases.

**TREATMENT**

Most patients seen in the ED with tendinopathy can be managed conservatively by resting the affected region, administering adequate pain medication, and referral to orthopedics or physical therapy for biomechanical rehabilitation and gradual eccentric load exercises (Box 86.1). Aseptic bursitis can be managed conservatively with joint protection, modification of activity, and pain control. Exceptions are olecranon bursitis and prepatellar bursitis, which have a moderate risk of being infected, most likely with *S. aureus*. These bursae require needle aspiration and treatment with antibiotics until culture results are negative. Documentation should support the clinical suspicion of infection (see the Documentation box).

**BOX 86.1 Treatment of Tendinopathy and Aseptic Bursitis**

*Rest*  
Ice for 24 to 48 hours after trauma  
Immobilization of the involved tendon  
Aspiration of the swollen bursa  
Circumferential compression band for the swollen bursa  
Oral analgesics tailored to the patient
Patients should rest the involved joint. Many patients with tendinopathy benefit from splinting followed by graduated range-of-motion exercises. Shoulders should not be immobilized for more than a few days because of the risk for adhesive capsulitis. Patients with superficial bursitis should have a compression dressing with an elastic bandage applied to prevent recurrent swelling after drainage of the bursa.

Nonsteroidal antiinflammatory drugs (NSAIDs) provide pain relief when compared with placebo and are well ingrained in the literature as treatment of both tendinopathy and bursitis. Because tendinopathies are now thought to be due to degenerative changes and abnormal healing responses, NSAIDs may not provide any additional benefit over other oral analgesics such as acetaminophen. NSAIDs have not been found to improve healing in patients with chronic tendinopathy and probably should not be used long-term for the management of recurrent pain. Further research is needed in this area. Oral analgesia should therefore be tailored to the patient. Regardless of the medication chosen, a short (1- to 2-week) course of oral analgesia should be administered as first-line treatment along with rest and modification of activity.

Glucocorticoid injections are often used in treating refractory rotator cuff tendinitis, de Quervain tendinitis, trigger finger, subacromial bursitis, trochanteric bursitis, and olecranon bursitis, although good-quality research to support their use is lacking. Complications of intrabursal injections are infection, local subcutaneous atrophy, bleeding, postinjection flare as a result of the release of microcrystals, and tendon rupture. Steroid injections are best managed by the follow-up physician after conservative measures have failed and culture results have definitively ruled out infection.

Multiple alternative treatments of chronic tendinopathy exist as well, including massage, stretching, cryotherapy, heat, therapeutic ultrasound, laser, orthotics, and various types of tendon injections. Evidence to support the use of these treatments is lacking. Some evidence supports eccentric load rehabilitation exercises for the treatment of chronic tendinopathy.

**ADMISSION AND DISCHARGE**

Most patients can be managed conservatively as outpatients as long as close follow-up is ensured (see the Patient Teaching Tips box). Referral to the primary medical physician, orthopedic surgery, and physical therapy is appropriate. Patients who undergo fluid aspiration of bursitis should follow up within 48 hours for culture results. Otherwise, patients may schedule follow-up within 1 to 2 weeks so that further treatment can be initiated if conservative measures fail. Patients with suppurative tenosynovitis or septic bursitis require admission for intravenous antibiotics and consultation with orthopedic surgery for incision and drainage.

**PATIENT TEACHING TIPS**

Instructions should be given regarding proper rest, analgesia, and immobilization.

If a joint or bursa is aspirated, prompt follow-up must be obtained for culture results.

Septic bursitis requires antistaphylococcal antibiotics and immediate orthopedic consultation. Patients with systemic symptoms require admission for intravenous antibiotics and operative washout.

Patients should call their primary provider or return to the emergency department for the following:

- Increased pain, swelling, or redness around the area
- Fever
- Inability to move a joint because of pain

Injuries to the Shoulder Girdle and Humerus

M. Scott Linscott

DISLOCATIONS
The most common dislocations are glenohumeral (85% being anterior), followed by acromioclavicular, sternoclavicular, and the very rare dislocation of the entire shoulder girdle from the thorax.

SOFT TISSUE INJURIES
The most common soft tissue injuries are the shoulder impingement syndromes, including subacromial tendinitis and bursitis with rotator cuff tears (95% are chronic and 5% acute), as well as tendinitis and rupture of the long head of the biceps tendon.

PATHOPHYSIOLOGY
The shoulder girdle connects the upper extremity to the thorax and axial skeleton. It consists of three bones (scapula, clavicle, and humerus), three joints (sternoclavicular, acromioclavicular, and glenohumeral), and one articulation (scapulothoracic). Injuries to the shoulder girdle include dis-articulation (rare), fractures, ligament sprains, joint dislocations, musculotendinous strains, and contusions, as well as injuries to the nerves and vascular structures of the shoulder girdle and humerus.

The scapula and clavicle are attached to the axial skeleton by ligaments at the sternoclavicular joint and by muscles from the blade or body of the scapula to the thorax. The clavicle is attached to scapula by the coracoclavicular and acromioclavicular ligaments. The coracoacromial ligament serves as the roof of the coracoacromial arch, beneath which the neurovascular bundle traverses (Figs. 87.1 and 87.2).

PRESENTING SIGNS AND SYMPTOMS

STERNOCLAVICULAR JOINT SPRAINS AND DISLOCATIONS
These injuries are graded as type I, a simple sprain of the joint; type II, subluxation of the joint, either anterior or posterior; and type III, complete dislocation of the joint. Dislocation usually results from a lateral force applied to the shoulder and an indirect force applied to either a rolled-back shoulder.
(anterior dislocation) or a rolled-in shoulder (posterior dislocation). Posterior dislocations are potentially life-threatening because the dislocated medial head of the clavicle may cause pneumothorax or injuries to the great vessels, esophagus, or trachea (all structures in the superior mediastinum).

The patient complains of severe pain in the affected sternoclavicular joint. In anterior dislocations, the protruding medial end of the clavicle is visible, easily palpable, and tender. In posterior dislocations, there is often a cavity where the medial end of the clavicle would normally lie, which is especially noticeable when compared with the uninjured side. Patients with posterior dislocations may also have signs and symptoms of pneumothorax, vascular occlusion, and esophageal or tracheal injury. Routine radiographs may not be diagnostic, and computed tomography (CT) is usually required to make the diagnosis. This should always be performed with intravenous (IV) contrast media when a posterior sternoclavicular dislocation is suspected to rule out injuries to the superior mediastinal vascular structures (Fig. 87.3).

**ACROMIOCLAVICULAR JOINT DISLOCATION OR SEPARATION**

Acromioclavicular separations are generally caused by a fall onto the point of the shoulder or acromioclavicular joint with the arm adducted (thus the lay term shoulder pointer to describe this injury). It is caused less frequently by a fall onto the outstretched arm in extreme abduction, which drives the acromion below the clavicle. Acromioclavicular separations are classified as six types, although only the first three (I to III) are commonly seen. Types IV to VI are very uncommon and usually require surgical repair. In type I acromioclavicular separations, the acromioclavicular ligaments are partially torn and the coracoclavicular ligaments are intact, which results in less than 50% superior dislocation or separation of the clavicle from the acromion (Fig. 87.4, A to C). In type II injuries, the acromioclavicular ligaments are completely torn and the coracoclavicular ligaments are stretched or partially torn, which results in at least 50% superior dislocation or separation of the clavicle from the acromion. In type III injuries, both the acromioclavicular and coracoclavicular ligaments are completely torn, with complete superior dislocation or separation of the clavicle from the acromion.
The patient complains of severe pain in the acromioclavicular joint. Type I dislocations are characterized by tenderness and some swelling over the acromioclavicular joint, with little or no tenderness over the distal end of the clavicle and coracoid process. With type II dislocations, patients have tenderness and more swelling over the acromioclavicular joint and some tenderness over the coracoid process. In type III dislocations, the clavicle is obviously dislocated superiorly when the patient is sitting or standing, with less deformity noted when the patient is supine. Shoulder radiographs may miss an acromioclavicular separation if the radiograph is taken with the patient supine. Acromioclavicular views (a single radiograph that includes both acromioclavicular joints) should be taken with patients in the sitting or standing position and the arms unsupported. In type I injuries there is less than 50% cephalad dislocation of the clavicle on the acromion of the affected shoulder. Type II injuries are marked by greater than 50% cephalad displacement of the clavicle on the acromion on the affected side. In type III dislocations, complete dislocation is seen on sitting or standing films. Use of weight-bearing films (the patient holds weights with the affected arm) is of no benefit.\

**CLAVICLE FRACTURES**

The most common mechanism of injury is a medially directed blow to the shoulder, usually from a ground-level fall. Children frequently have a bowing deformity or a greenstick fracture, whereas in adults the fracture fragments are often significantly displaced. Clavicle fractures are divided into proximal third, middle third, and lateral third. Lateral third fractures are divided into types I, II, and III (Fig. 87.5). Type II lateral third fractures are relatively unstable because the coracoclavicular ligament has been disrupted.

Patients complain of severe pain at the site of the fracture. They may support the adducted arm on the injured side with the other hand. A deformity is usually obvious, and the fracture site is tender. The diagnosis is made by radiography of the injured clavicle. If a type II distal third clavicle fracture is suspected, both supine and upright films will reveal the degree of instability of the fracture.

**SCAPULA FRACTURES**

Scapular fractures are typically associated with high-energy force and are thus often associated with significant life-threatening injuries, especially injuries to the ipsilateral ribs, pleura, and lungs. Most scapular fractures are caused by a direct blow, although fractures of the glenoid and scapular neck may occur as a result of a fall on an outstretched arm.\

The patient complains of pain at the site of the fracture. Any movement of the ipsilateral arm will exacerbate the pain, especially with fractures of the glenoid. Fractures of the scapular spine are usually seen clearly on plain films. However, fractures of the neck and the glenoid may not be seen, and if suspected, a CT scan of the scapula should be obtained.

**GLENOHUMERAL DISLOCATIONS**

Dislocations of the glenohumeral joint are divided into anterior, posterior, and inferior (luxatio erecta). Most glenohumeral dislocations are anterior and are caused by an indirect...
force such as abduction, extension, and external rotation; however, they are occasionally caused by a direct blow to the proximal end of the humerus.

Patients generally have severe pain in the glenohumeral joint and hold the affected arm in adduction and internal rotation. There is lack of the normal contour, with a depression where the humeral head would normally reside. Patients report extreme pain in the joint with any attempted movement of the arm. Anteroposterior (AP) and axillary or transthoracic lateral radiographic views should be obtained in all patients with suspected dislocations, even if the patient has a history of multiple dislocations, because occasionally an associated fracture of the proximal end of the humerus or a posterior dislocation will be present. If displaced fractures of the glenoid or proximal end of the humerus are suggested on plain radiographs, CT scans of the shoulder should be obtained. Though rare, with luxatio the patient has the classic picture of holding the arm in marked adduction and over the head (Fig. 87.7). The radiograph reveals the humeral head to lie inferior to the glenoid and the humeral shaft adducted superiorly (Fig. 87.8).

**PROXIMAL HUMERUS FRACTURES**

The two mechanisms that most commonly cause fractures of the proximal end of the humerus are (1) a direct blow to the lateral aspect of the upper part of the arm and (2) indirect forces generated by a fall on an outstretched arm. The position of the humeral shaft in relation to the proximal fragments depends on whether the fall is onto an abducted or adducted arm.

The Neer fracture classification is most commonly used and is based on the position of the articular segment, the greater and lesser tuberosities, and the humeral shaft. According to the Neer classification, a fracture is considered displaced if any major fracture fragment is displaced 1 cm or more or is angulated greater than 45 degrees. Fractures are classified as
CHAPTER 87  INJURIES TO THE SHOULDER GIRDLE AND Humerus

one-, two-, three-, or four-part fractures and are usually differentiated along the classic epiphyseal lines (anatomic neck, surgical neck, greater tuberosity, and lesser tuberosity) (Fig. 87.9).

The patient has severe pain in the proximal end of the humerus. An obvious deformity may be present, as well as swelling and extreme tenderness over the proximal end of the humerus. The trauma radiographic series recommended by Neer, as well as an AP internal rotation view and an axillary lateral view, provides the most complete diagnostic information. A CT scan of the shoulder may be necessary to better define the extent of injury.

HUMERAL SHAFT FRACTURES

Humeral shaft fractures are almost always caused by a direct blow to the bone, and this mechanism usually results in a transverse fracture. Occasionally, a fall onto an outstretched hand or a severe twisting force brought about by supination or pronation or by twisting of the entire arm may result in spiral fractures.

Symptoms include pain and deformity at the fracture site. In addition, the fracture is usually very unstable. If the radial nerve is injured, the patient will not be able to extend the wrist or fingers and generally has decreased sensation on the dorsum of the hand. The diagnosis is based on radiographs of the humerus. As with all long-bone fractures, the joints above and below the fracture—in this case the shoulder and elbow—should also be radiographed.

DISTAL HUMERUS (SUPRACONDYLAR) FRACTURES

Supracondylar fractures are classified as either flexion or extension fractures and occur almost exclusively in children, usually between the age of 4 and 10 years. More than 95% of these fractures are the extension type and occur when the child falls onto an outstretched arm with the elbow in full extension or hyperextension. In the flexion-type fracture, the child falls onto the arm with the elbow flexed.

The patient is generally seen holding the injured arm in extension with the unaffected hand. Swelling, as well as tenderness to palpation over the distal end of the humerus, is typical. An S-shaped deformity may be present if significant displacement of the fracture fragments has occurred. The patient resists any attempt to flex or extend the elbow. Elbow radiographs (AP and lateral views) should be obtained. The fracture will often be visible only on the lateral view unless fracture fragments are significantly displaced. Normally, the anterior humeral line should pass through the capitellum (Fig. 87.10, A and B). If the capitellum is anterior to the anterior humeral line, it is diagnostic of a flexion-type supracondylar fracture in a child. If the capitellum is posterior to the anterior humeral line, it is diagnostic of an extension-type supracondylar fracture. Based on radiographic findings, extension fractures are often classified into three types: type I has minimal or no displacement; type II is a displaced fracture with the posterior cortex intact; and type III is a completely displaced fracture, with both the anterior and posterior cortices disrupted.

ROTATOR CUFF TENDINITIS/SUBACROMIAL BURSITIS, ROTATOR CUFF TEARS, AND IMPINGEMENT SYNDROMES

These three disorders have much in common; rotator cuff tears are the end result of rotator cuff tendinitis and subacromial bursitis. Most rotator cuff tears occur in patients older than 40 years and result from long-term degeneration and entrapment of the rotator cuff tendons as they pass between the humeral head and the acromion (impingement syndrome).

The injury occurs with a sudden, powerful elevation of the arm (as when grabbing a tree limb during a fall). Occasionally, the injury occurs in weight lifters and in patients who fall onto
the shoulder. In younger patients, these injuries frequently result in avulsion of bone because their tendons are normal.

The patient complains of pain over the proximal end of the humerus, where the rotator cuff tendons attach to the greater tuberosity. Significant pain is felt with both active and passive abduction of the shoulder. In other impingement syndromes (supraspinatus tendinitis and subacromial bursitis), the symptoms are similar, but with less tenderness over the rotator cuff and greater tenderness proximally. The drop arm test is positive if a significant rotator cuff tear has occurred. The patient extends the injured arm to 90 degrees and the operator lightly taps the wrist or forearm. In a positive test, the patient suddenly drops the arm. In addition, the patient cannot slowly lower the arm from the abducted position—rather, it drops suddenly to the side. In patients with rotator cuff tendinitis or subacromial bursitis, significant pain occurs with abduction, but the drop arm test is negative.

**TENOSYNOVITIS AND RUPTURE OF THE LONG HEAD OF THE BICEPS TENDON**

The long head of the biceps tendon inserts into the glenoid rim and traverses the bicipital groove between the greater and lesser tuberosities. The tendon is irritated by multiple shoulder

CHAPTER 87

Closed reduction of an anterior dislocation is accomplished with the patient in the supine position and rolled blankets placed between the shoulder blades. Significant downward pressure on the distal and proximal ends of the clavicle with elevation of the proximal end usually reduces the dislocation (Fig. 87.12). If reduction is accomplished, the patient should be placed immediately in a clavicle or figure-of-eight splint to maintain the reduction (Fig. 87.13), as well as an arm sling and swath (Figs. 87.14 and 87.15). Patients with posterior sternoclavicular dislocations require immediate orthopedic consultation; open reduction is usually necessary. Most reductions should be performed in the operating room with thoracic surgery backup in the event of injury to the superior mediastinal structures. Complications include pneumothorax and vascular, esophageal, and tracheal injuries. Although nonoperative attempts at reduction are occasionally successful, most patients with posterior sternoclavicular dislocations require

ADHESIVE CAPSULITIS

Adhesive capsulitis is caused by inflammation within the glenohumeral joint capsule, which leads to the formation of adhesions within the joint capsule and marked limitation of range of motion of the shoulder. The exact mechanism is unclear; however, this disease usually results from prolonged immobilization of the shoulder joint, particularly when associated with inflammation, such as in subacromial bursitis.

In most cases the nondominant arm is affected and the patient experiences pain with minimal activity. The pain is generally worse at night. There is tenderness in the subacromial area and marked limitation of glenohumeral motion in all ranges, especially abduction and rotation. The diagnosis is made primarily on the basis of the symptoms and signs described previously. Radiographs are typically normal. Arthroscopy or arthrography may be diagnostic, but these modalities are invasive and should be avoided if possible. Adhesive capsulitis is usually due to prolonged immobilization of the shoulder in patients with subacromial bursitis or rotator cuff tendinitis.

TREATMENT

STERNOCLAVICULAR DISLOCATION

Closed reduction of an anterior dislocation is accomplished with the patient in the supine position and rolled blankets placed between the shoulder blades. Significant downward pressure on the distal and proximal ends of the clavicle with elevation of the proximal end usually reduces the dislocation (Fig. 87.12). If reduction is accomplished, the patient should be placed immediately in a clavicle or figure-of-eight splint to maintain the reduction (Fig. 87.13), as well as an arm sling and swath (Figs. 87.14 and 87.15). Patients with posterior sternoclavicular dislocations require immediate orthopedic consultation; open reduction is usually necessary. Most reductions should be performed in the operating room with thoracic surgery backup in the event of injury to the superior mediastinal structures. Complications include pneumothorax and vascular, esophageal, and tracheal injuries. TREATMENT

STERNOCLAVICULAR DISLOCATION

Closed reduction of an anterior dislocation is accomplished with the patient in the supine position and rolled blankets placed between the shoulder blades. Significant downward pressure on the distal and proximal ends of the clavicle with elevation of the proximal end usually reduces the dislocation (Fig. 87.12). If reduction is accomplished, the patient should be placed immediately in a clavicle or figure-of-eight splint to maintain the reduction (Fig. 87.13), as well as an arm sling and swath (Figs. 87.14 and 87.15). Patients with posterior sternoclavicular dislocations require immediate orthopedic consultation; open reduction is usually necessary. Most reductions should be performed in the operating room with thoracic surgery backup in the event of injury to the superior mediastinal structures. Complications include pneumothorax and vascular, esophageal, and tracheal injuries. Although nonoperative attempts at reduction are occasionally successful, most patients with posterior sternoclavicular dislocations require
Sling or a sling and swath for the ipsilateral arm). Even markedly displaced fractures generally heal without surgical intervention. Some attempts at closed reduction may be appropriate if these fractures are markedly displaced or if significant skin tenting is noted. Many orthopedic surgeons believe that surgical intervention is indicated only if the fracture is open, if there is marked diastasis between the two fracture fragments that cannot be corrected with closed reduction, or in some cases of a type II distal clavicle fracture. Recently, one study showed that surgical repair of middle third clavicle fractures may be cost-effective after 9 years when compared with nonsurgical therapy. However, even type II distal third clavicle fractures may do well with nonoperative therapy, although nonunion occurs frequently and surgical therapy is probably preferred.

For patients with middle and proximal third fractures, a figure-of-eight clavicle splint may decrease the pain and, in occasional patients, help keep the fracture reduced. However, such splints are primarily for the patient’s comfort and should not be used if their application increases pain from the fracture, which it often does, especially with lateral third clavicle fractures. No evidence has shown any difference in healing time, severity, duration of pain, or any other parameter with an arm sling versus a figure-of-eight clavicle splint or both.

**SCAPULA FRACTURES**

Most scapular fractures are treated nonsurgically with a sling, ice, analgesics, and range-of-motion exercises. Displaced fractures of the glenoid, neck, and coracoid and some acromial fractures may need ORIF; patients with such fractures should be referred for consultation with an orthopedic surgeon.

**GLENOHUMERAL DISLOCATIONS**

**Anterior Dislocations**

Multiple techniques for closed reduction of anterior glenohumeral dislocations have been recommended. The three main categories are scapular manipulation, traction, and leverage. The hippocratic method (foot in the axilla with traction on the extended arm) and the Kocher maneuver (traction, adduction, internal rotation) should not be used because of the increased incidence of brachial plexus injuries with the hippocratic method and the increased incidence of proximal humerus fractures with the Kocher maneuver. For almost all reduction techniques to be successful, adequate sedation/analgesia or anesthesia must be obtained. Conscious sedation with IV fentanyl (50 to 100 mcg) and IV midazolam (1 to 3 mg) is adequate for most reductions. However, some patients require deep sedation with propofol or etomidate, and occasionally a patient may require general anesthesia to accomplish the reduction. Frequently, injecting 10 to 20 mL of 1% lidocaine or 0.25% bupivacaine into the vacated glenohumeral joint will significantly facilitate reduction of the dislocation.

Several methods commonly used to reduce anterior glenohumeral dislocations are described in the following sections.

**SCAPULAR MANIPULATION**

Ideally, the patient is in the prone position with the dislocated arm hanging over the edge of the stretcher. Traction is applied to the arm, and the operator pushes the tip of the scapula medially while stabilizing the clavicle.
upper part of the scapula (Fig. 87.16). If the patient insists on sitting up, this same technique can be combined with a modified hippocratic method in which one operator applies countertraction superiorly with a sheet sling in the axilla, another operator places traction on the arm, and a third operator manipulates the scapula. This is the technique of choice for the author. It requires relatively little sedation or analgesia and is successful in more than 90% of cases.\(^1\)

**EXTERNAL ROTATION** With the patient supine, the affected arm is adducted close to the thorax. The elbow is flexed to 90 degrees and the operator very slowly externally rotates the arm without applying longitudinal traction. This method is safe, easily learned, and relatively atraumatic for the patient\(^2\)\(^9\) (Fig. 87.17).

**MODIFIED HIPPOCRATIC (TRACTION-COUNTERTRACTION) METHOD** With the patient supine, the elbow is slightly abducted and flexed to 90 degrees. The operator ties a sheet around his or her waist and to the proximal end of the patient’s forearm. An assistant slings another sheet around the thorax and under the affected armpit and ties it around his or her own waist. The operator and the assistant pull in opposite directions with their arms and bodies (Fig. 87.18).

**STIMSON METHOD** With the patient prone, the affected arm is dangled over the edge of the stretcher and a 10- to 20-lb weight is attached to the wrist to produce constant, gentle traction. This method is one of the oldest and has the advantage of not requiring the physician to be present for the reduction and probably being the least traumatic for the patient. The disadvantage is that it often takes 20 or more minutes to complete the reduction and ties up a nurse for this period if the patient has been consciously sedated (Fig. 87.19). Several other techniques have also been proposed for reduction of anterior glenohumeral dislocations.\(^2\)!$^1$\(^{25}\)
**PROXIMAL HUMERUS FRACTURES**

With a glenohumeral dislocation, the patient will usually need ORIF to reduce the dislocation and repair the proximal humeral fracture. If the fractures are not displaced (<1 cm of displacement), wearing a sling or a sling and swath may be all the treatment that is required. If significant displacement remains after closed reduction, ORIF will be necessary. Orthopedic consultation should be obtained in almost all cases.

Successful treatment is most dependent on early mobility. Prolonged immobilization without range-of-motion exercises often results in adhesive capsulitis or a marked reduction in mobility of the glenohumeral joint. Patients should be encouraged to perform circumduction range-of-motion exercises after a few days of immobilization, especially elderly patients (Fig. 87.21).

**HUMERAL SHAFT FRACTURES**

Most humeral shaft fractures can be treated conservatively. If the fracture fragments are minimally displaced, no reduction is necessary. If the fragments are widely separated, reduction may be carried out before splinting. If the fracture fragments are in reasonable apposition (within 1 to 2 inches) following the reduction, the most commonly used splinting technique is the coaptation or sugar-tong splint, whereby a 5-inch plaster or Orthoglass splint is applied over the shoulder, down the lateral side of the upper part of the arm, around the elbow, and up the medial side of the upper part of the arm near the axilla. The arm is then placed in a sling with the sling around the wrist so that the weight of the splint will bring the fracture fragments together (Fig. 87.22). If the fracture fragments are separated more than 2 inches after reduction or if a spiral fracture is present, the hanging cast technique may be used. A lightweight cast is applied 1 to 2 inches proximal to the fracture site up to the palmar crease of the hand. The elbow is flexed to 90 degrees and a loop is placed at the wrist either on the dorsal side to reduce lateral angulation or on the volar side to reduce medial angulation (Fig. 87.23). The hanging cast has the disadvantage of needing gravity for traction; therefore, patients must remain upright at all times, even during sleep. Many patients cannot tolerate this.
The most common and most feared complication of humeral shaft fractures is radial nerve injury. If nerve function is lost before reduction, most authorities treat it expectantly. Most of the time nerve function returns because the nerve has been either contused or stretched. After reduction, function of the radial nerve should again be tested. If radial nerve function is compromised but was normal before reduction, most authorities recommend ORIF because the probability is high that the radial nerve is entrapped within the fracture.

**SUPRACONDYLAR FRACTURES**

Type I supracondylar fractures are treated with a long arm splint and the elbow flexed to 90 degrees. The arm is placed in a sling. Protected active range-of-motion exercises are begun in 3 to 4 weeks.

Type II fractures require reduction even though they are minimally displaced. Following reduction, a long arm splint is applied with the elbow flexed to 100 to 120 degrees. Flexion greater than 90 degrees places tension on the intact posterior periosteum to maintain the reduction. Because this degree of hyperextension may compromise neurovascular structures volar to the elbow, careful attention should be paid to ensure that this complication does not arise, especially in the first 2 to 3 days after the fracture. Orthopedic consultation should be obtained in all cases.

Type III injuries are problematic because they may increase the chance for a varus deformity and are more likely to cause injury to the neurovascular structures passing through the elbow. Rarely should an attempt be made to reduce these fractures in the ED. The only exception might be the unavailability of immediate orthopedic consultation for a patient who has an obviously occluded brachial artery. The vast majority of these patients should be taken to the operating room immediately and undergo either closed or open reduction. Orthopedic consultation is mandatory in all cases.

The most common complication is loss of the normal carrying angle, which results in a cubitus varus deformity. This complication has decreased in incidence as the practice of percutaneous pinning of the fracture has evolved. More serious complications of supracondylar fractures include brachial artery injury and injuries to the radial, median, and ulnar nerves. Most often these injuries are due to contusion or stretching of the nerves, and full recovery is the rule.

**ROTATOR CUFF TENDINITIS/SUBACROMIAL BURSITIS, ROTATOR CUFF TEARS, AND IMPINGEMENT SYNDROMES**

Treatment depends on the degree of disability (incomplete versus complete tear), the patient’s age, and the patient’s activity level. In patients with tendinitis or subacromial bursitis, an injection into the subacromial bursa usually results in relief of pain. In young, active patients with significant rotator cuff tears, arthroscopic repair is indicated. In older patients with a sedentary lifestyle, repair should rarely be attempted because the outcome is often worse than that with conservative therapy. For evaluation, patients should be referred for consultation with an orthopedist who specializes in shoulder injuries.

**TENOSYNOVITIS AND RUPTURE OF THE LONG HEAD OF THE BICEPS TENDON**

Conservative treatment consists of a sling and nonsteroidal antiinflammatory drugs (NSAIDs). If after a week of immobilization the patient continues to have pain, the bicipital canal can be injected with a combined local anesthetic and steroid. Range-of-motion exercises should be performed daily to prevent adhesive tenosynovitis.

**ADHESIVE CAPSULITIS**

The most important form of therapy should be directed at prevention of this problem. All patients with shoulder injuries or inflammation should be encouraged to perform circumduction range-of-motion exercises daily to prevent adhesive capsulitis. Conservative treatment consists of a gentle exercise program, NSAIDs, and corticosteroid injections. Such treatment results in significant improvement in many patients;
however, many others require the adhesions to be broken up by putting the shoulder through full range of motion under general anesthesia.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

**STERNOCLAVICULAR STRAINS, SUBLUXATIONS, AND DISLOCATIONS**

Anterior dislocations can be reduced in the ED. The patient should be placed in a sling and swath and be told to wear it for 2 to 3 weeks and follow up with an orthopedic surgeon. If an anterior dislocation cannot be reduced in the ED, the patient should be placed in a sling and figure-of-eight clavicle splint and be referred to an orthopedic surgeon. A patient with a posterior dislocation should undergo CT of the sternoclavicular joint and be seen urgently by an orthopedic surgeon. The patient must also be seen by a cardiothoracic surgeon if injury to a superior mediastinal structure is suspected.

**ACROMIOCLAVICULAR SEPARATION OR DISLOCATION**

Patients with a type I or II separation should be put in a sling or a sling and swath for their comfort. They should be treated with ice and analgesics and be told to follow up with their primary care physician. Patients with type III separations should be put into a sling, be told to apply ice to the injury, and be referred for follow-up consultation with an orthopedic surgeon within 1 to 2 weeks. Most type III fractures should be treated conservatively. Although some orthopedic surgeons may elect to perform open reduction of these injuries in an athlete who uses the injured arm in overhead activities (e.g., baseball pitcher, football quarterback), no good evidence has shown a difference in outcome with surgical versus nonsurgical therapy, even in these patients. Type IV, V, and VI injuries are usually severe, and these patients should be referred to an orthopedic surgeon for consultation because most will require ORIF.

**CLAVICLE FRACTURES**

The only indication for immediate surgery is an open fracture or fractures with neurovascular compromise. Some orthopaedic surgeons would consider a significantly displaced type II distal third clavicle fracture, any fracture with skin tenting, or any widely displaced middle or proximal third clavicle fracture as an orthopaedic urgency. All such patients should be referred immediately to an orthopaedic surgeon. If patients are to be discharged, they should be put in a sling, be told to put ice on their injured clavicle, and be prescribed potent opioid analgesics. Patients should leave their arm in a sling (with a figure-of-eight bandage if it provides additional comfort). Patients should be told to perform circumduction range-of-motion exercises at least once daily to prevent adhesive capsulitis. The sling should be left on for 2 to 4 weeks in children younger than 14 years and for 4 to 8 weeks in adolescents and adults. Referral to an orthopedic surgeon is necessary only for patients with severely displaced fractures (>20 mm of shortening), open fractures, fractures associated with neurovascular injury or skin tenting, and type II distal third clavicle fractures. Complications are uncommon and consist of osteoarthritis of the acromioclavicular joint (in type II and III distal third clavicle fractures) and nonunion in type II distal third clavicle fractures (primarily a cosmetic issue).

**SCAPULA FRACTURES**

Most scapular fractures heal without surgery, and patients should be discharged with a sling, instructions to apply ice, and analgesics, as well as arrangements for follow-up with an orthopedic surgeon. Patients with fractures of the scapular neck and glenoid that are widely displaced or angulated may need ORIF and should be referred immediately to an orthopedic surgeon. These fractures are associated with internal injuries, which should be ruled out before discharge.

**GLENOHUMERAL DISLOCATIONS**

Most dislocations can be reduced with some type of conscious sedation in the ED. In some cases the relocation will be unsuccessful and the patient must be taken to the operating room for relocation. Following relocation, the patient may be discharged with a sling or a sling and swath. The sling should be kept on for 3 to 5 weeks, and the patient should perform circumduction range-of-motion exercises until the sling is removed. Complications include fracturing of the humerus during reduction and injury to the axillary nerve, which should be checked before and after reduction. Prereduction radiographs are recommended. However, routinely obtaining postreduction radiographs is controversial, especially if the patient is asymptomatic. The sling should be left on for approximately 4 weeks.

**PROXIMAL HUMERAL FRACTURES**

Most patients with these fractures do not require admission unless it is needed for pain control. Successful treatment is most dependent on early mobility. Prolonged immobilization without range-of-motion exercises often results in adhesive capsulitis or a marked reduction in mobility of the glenohumeral joint. Patients should be encouraged to perform circumduction range-of-motion exercises after a few days of immobilization, especially elderly patients.
HUMERAL SHAFT FRACTURES
Unless the fracture is open, most patients can be discharged home. The coaptation splint or hanging cast should remain in place until the patient sees the orthopedic surgeon 2 to 3 days following the injury. The patient should be given potent oral analgesics for pain.

SUPRACONDYLAR HUMERAL FRACTURES
Patients with type I fractures are usually discharged with a long arm splint in 90 degrees of flexion at the elbow and orthopedic follow-up scheduled within 2 weeks. Patients with type II and III fractures are generally admitted to the hospital and undergo ORIF. The most common complication is loss of the normal carrying angle, which results in a cubitus varus deformity. This complication has decreased in incidence as the practice of percutaneous pinning of the fracture has evolved. More serious complications of supracondylar fractures include brachial artery injury and injuries to the radial, median, and ulnar nerves. Most often these injuries are due to contusion or stretching of the nerves, and full recovery is the rule.

ROTATOR CUFF TENDINITIS/SUBACROMIAL BURSITIS, ROTATOR CUFF TEARS, AND IMPINGEMENT SYNDROMES
Conservative therapy for rotator cuff tears consists of improving the patient’s ability to abduct the arm. Having the patient “crawl up the wall” with the affected hand until the pain is unbearable and repeat this exercise daily is beneficial. In addition, subacromial injection of a local anesthetic and steroid mixture reduces pain and allows greater range of motion. This should probably be limited to two or three times per year because of the tendency for steroids to cause tendon rupture. Treatment of subacromial bursitis and supraspinatus tendinitis is similar to that for conservative therapy for rotator cuff tears, with initial treatment consisting of the application of ice and NSAIDs and, in refractory cases, subacromial steroid or local anesthetic injections.

88 Forearm Fractures
Trevor J. Mills

KEY POINTS
- The goal of treatment of forearm fractures is to restore length, correct angulation, and ideally, achieve normal function.
- Radiographs of the proximal and distal joints of patients with a forearm fracture should always be considered to rule out concurrent dislocations (i.e., Monteggia fracture).

EPIDEMIOLOGY
Injury is a leading cause of mortality, morbidity, and lost days of work. The annual health care cost of injuries exceeds $9.2 billion. Traumatic injuries result in more than 34 million emergency department (ED) visits each year. The highest rate of injuries occurs in persons between the ages of 15 and 24 years. Likewise, forearm fractures are commonly seen in young adults but have a bimodal distribution, with a second increased incidence in the elderly.

PATHOPHYSIOLOGY
The bones of the forearm consist of the radius and ulna. These two bones lie in parallel and are connected by joint capsules at the elbow and at the wrist, whereas the shafts are interlocked by a fibrous interosseus membrane. Most forearm fractures are caused by a sudden force, such as a fall on an outstretched arm. Because of the interlocking joint capsules, interosseus membrane, and contraction of the forearm muscles, multiple fractures, displaced fragments, and concurrent dislocations may be present. Alternatively, forearm fractures may be due to smaller repetitive injuries, which result in a stress fracture over time. Any pathophysiologic process that reduces the integrity of the bone, such as osteopenia, osteomyelitis, and bone metastasis, increases the likelihood of fracture, even with normal external stress.

PRESENTING SIGNS AND SYMPTOMS
Symptoms of forearm fractures include pain, forearm edema, forearm ecchymosis, abnormal or reduced mobility from the wrist through the elbow, and complaints of neurovascular compromise. Findings on physical examination can include obvious bony deformity; shortening of the forearm; crepitus; tenderness to palpation of the forearm; joint effusions; abnormal mobility of the wrist, forearm, or elbow; and neurologic and vascular deficits of the forearm, wrist, or hand.

Box 88.1 lists the signs and symptoms of fractures and complications that suggest serious injury.

In general, forearm fractures are classified by the bone (or bones) involved, anatomic location, trajectory of the fracture and alignment of the fracture fragments, and the presence of angulation, rotation, comminution, and concurrent dislocations. All fractures should be further described as open or closed, and the presence (or absence) of distal neurologic and vascular function should be noted (Fig. 88.1).

Types of forearm fractures that are frequently mentioned in the medical literature are described in Table 88.1.

PEDIATRIC FRACTURES
Forearm fractures in the pediatric population include several additional entities because children have a plastic bone matrix and active growth plates, both of which contribute to unique fractures (Table 88.2). In children, when an external force bends a long bone, one side of the cortex may be disrupted while the other side remains intact (greenstick fracture).
Alternatively, a deformity of the bone may occur without an obvious fracture line (plastic deformity). With compression, buckling of the cortex may be seen (torus fracture). Depending on the age of the child, fractures through the various growth plates of the elbow and wrist may also occur (Salter-Harris fractures).5

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis for forearm fractures includes any soft tissue injury to the forearm, in addition to acute skin, soft tissue, and joint infections (Box 88.2). Some clinical aspects of acute arterial occlusion, as well as venous thrombosis, may mimic forearm fractures. Any acute neurologic change, including paresthesias, weakness, and functional loss, should be considered along with forearm fractures. Two normal variants sometimes mistaken for forearm fractures on radiographs are normal growth plates in children and nutrient vessels.

The orthopedic literature often recommends radiographs of forearm fractures if they are close to the joint (either elbow and below the injury (Fig. 88.2; Table 88.3). This is true for forearm fractures if they are close to the joint (either elbow or wrist) or are suspected of having a concurrent dislocation (Fig. 88.3).
Fig. 88.2 Radiographs demonstrating the need for at least two views of a fracture. In A (anteroposterior view), there appears to be good alignment; in B (lateral view), a large amount of displacement is obvious.

Disruption of the radioulnar joint must be suspected in patients with a fracture of the ulnar styloid, shortening of the radius (5 mm), or widening of the radioulnar joint (2 mm). ORIF will probably be required.

Because isolated proximal ulnar fractures are unusual, a Monteggia fracture must be suspected and specific attention paid to the radial head to assess for dislocation. Specific radiographs of the radioulnar joint should be obtained if dislocation is suspected because the overall forearm radiograph may not reveal subtle injury. A longitudinal line through the radial shaft and head must transverse the capitellum in all views. Open reduction with internal fixation (ORIF) will probably be required, although children may be treated with casting.

Galeazzi fractures are two to three times more common than Monteggia fractures and have the potential for higher morbidity as a result of disruption of the distal radioulnar joint accompanying fracture of the distal end of the radius.

AP, Anteroposterior.

Disruption of the radioulnar joint must be suspected in patients with a fracture of the ulnar styloid, shortening of the radius (5 mm), or widening of the radioulnar joint (2 mm). ORIF will probably be required.

Although most forearm fractures are evident on plain radiographs, occult fractures of the elbow may be difficult to interpret. One indication of an elbow fracture is the fat pad or sail sign, which indicates hemarthrosis of the elbow joint and thus a fracture.7

The fracture is probably unstable if it is comminuted.

TREATMENT

Prehospital treatment includes immobilization to reduce the development of further injury and help control pain. The mainstays of ED treatment include pain control, reduction of further injury, immobilization, and appropriate disposition. Pain control should include elevation of the arm and cooling via ice packs. Oral or parenteral pain medications are usually indicated, depending on the age and size of the patient and the amount of pain.

Reduction of further injury depends on the fracture. Patients with open fractures and suspected open fractures should be given early parenteral antibiotic therapy and tetanus prophylaxis (if indicated). Displaced fractures and fractures with associated dislocations require early relocation, either by the emergency physician in consultation with an orthopedic surgeon or, if the patient’s condition is unstable, by an orthopedic surgeon in the ED.9

The preferred method of fracture immobilization in the ED is splinting rather than casting because fracture edema will tend to increase in size over the first 24 hours. Specific splints for particular fractures are listed in Table 88.5.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients with forearm fractures can be classified into three categories: those who need immobilization with routine orthopedic follow-up, those who need interventions in the ED with very close follow-up, and those who should be admitted to the hospital.9

Admission criteria include all open fractures, fractures with suspected compartment syndrome or neurovascular compromise, and fractures (or fracture-dislocations) that cannot be
adequately reduced in the ED. Patients who have difficulty with pain control or social issues that reduce their ability to take care of their injuries may also require admission. Any suspicion of child abuse, interpersonal violence, or elder abuse may also necessitate admission.

Forearm injuries that require urgent orthopedic referral include unstable fractures, fractures that can be reduced and splinted but need further internal fixation, and dislocations that are reduced.

**TIPS AND TRICKS**

**Splinting Procedure**

Use extra padding on the elbow and wrist. Cast padding should be smooth to avoid pressure points. To avoid irregularities, use constant pressure (palms, not fingers) to shape the splint. Always repeat the distal neurovascular examination after the splint dries. If in doubt, splint flexion joints in the position of use and avoid flexion contractures.

**PRIORITY ACTIONS**

History: Elucidate mechanisms with a high potential for open fractures.

Physical examination: Check the joints above and below the injury, examine the skin for open wounds, and evaluate and reevaluate neurovascular status distal to the injury.

Radiography: Always look for a second fracture or associated dislocation.

Treatment: Antibiotic therapy is needed for patients with open fractures; early reduction of dislocations and displaced fractures is essential.

**DOCUMENTATION**

**History**
Details of the mechanism and circumstances (fall, penetrating trauma, motor vehicle collision)
Timing of the event; time elapsed before arrival at the emergency department
Concurrent medications, drugs, or alcohol use; allergies; last meal; immunizations
Past orthopedic injuries or surgeries; other surgeries

**Physical Examination**
Initial examination, including evaluation of motor, neurologic, and vascular function
Reexamination over time, including after any intervention (e.g., splinting)

**Diagnostic Studies**
Emergency department interpretation of radiographs, computed tomography scans, magnetic resonance images, and angiograms

**Medical Decision Making**
Indications for studies and choice of consultant
Discussion with the consultant and mutual care plan decisions

**Procedures**
Details of each procedure, including the type of splint or immobilization device used

**Patient Instructions**
Discussion of injuries and potential outcomes with the patient, family, or both
Discussion of splint care with the patient, family, or both
Documentation of pain medications prescribed or the recommended plan for breakthrough pain

Hand and Wrist Injuries

Sara W. Nelson and Michael A. Gibbs

KEY POINTS

- Irrigation is the greatest ally in preventing wound infections.
- The final step in the management of almost all hand and wrist injuries is effective splinting.
- All but the most minor hand and wrist injuries merit scheduled follow-up.

PERSPECTIVE

Effective use of the hand is such a fundamental human skill that none of us can imagine living without it. Injuries that threaten this vital function have an impact on patients of all ages and walks of life but tend to cluster in productive young adults who use their hands to make a living. It goes without saying that the stakes are high for both the patient and physician. Emergency physicians (EPs) must develop a sophisticated understanding of hand anatomy and function, as well as injury patterns and optimal management strategies.

EPIDEMIOLOGY

Annually, more than 16 million people suffer some form of hand injury, and more than 4.8 million will seek treatment of these injuries at the emergency department (ED).1 Traumatic injuries may include lacerations, fractures, and tendon or ligamentous injuries. Most injuries are readily identified in the ED, provided that the assessment is effective.2 Because the morbidity associated with undiagnosed, misdiagnosed, or mistreated hand injuries is significant, a high level of expertise is required of the EP.

PATHOPHYSIOLOGY

This chapter assumes that the reader is familiar with the basic structures of the hand. The back of the hand is referred to as the dorsal surface; the palm is called either the palmar or volar surface. The lateral borders of the hand are referred to as radial or ulnar. Movement may occur in any of these planes. Additionally, fingers may abduct away from or adduct toward an imaginary plane bisecting the third finger. The thumb has further planes of movement. In general, we refer to the digits by their numerical designations, but the common names are also acceptable—first (thumb), second (index finger), third (middle finger), fourth (ring finger), and fifth (little finger).

PRESENTING SIGNS AND SYMPTOMS

When assessing hand injuries, the history should focus on the mechanism of the injury, hand position at the time of the insult, perceived resultant functional impairment, and the time elapsed since the injury. Some mechanisms yield classic injury patterns, such as the jersey finger and mallet finger. Other injury patterns are known for their poor outcomes, such as fight bites or high-pressure injection injuries, and require specific managements. Some wounds are more prone to infection, such as crush injuries and grossly contaminated wounds.

During the history the patient’s hand dominance and career should also be ascertained and documented. Factors that may compromise wound healing, such as smoking, drug use, or an immunocompromised state, are important to document.2 Tetanus status should be verified.

Despite its complicated nature, the hand can be examined adequately in a short period. Developing a rapid, reproducible hand examination strategy and performing it regularly will decrease the chance of missing subtle injuries. Even when a specific injury is obvious, it is important to examine the entire hand to avoid overlooking less obvious, coincident injuries. Box 89.1 lists one approach to comprehensive assessment of the hand.

Assuming that no active bleeding is occurring and requires immediate attention, examination of the hand begins with inspection. All rings, watches, and other potentially constricting devices should be removed immediately.1 Lacerations and other disruptions in skin integrity are usually recognized easily; erythema, soft tissue swelling, and ecchymoses should also be noted. It is important to compare the general position of the hand with that of the unaffected side inasmuch as many fractures or tendon disruptions will cause characteristic deformities that are recognizable on inspection.

Vascular integrity should be determined by comparing skin temperature with that of the opposite hand, feeling for ulnar and radial pulses, and documenting intact and symmetric distal capillary refill.
BOX 89.1 Two-Minute Hand Examination

General
- General appearance
- Obvious deformity

Vascular
- Hemorrhage control
- Ulnar and radial pulses
- Capillary refill less than 2 seconds

Neurologic
- Ulnar
  - Sensation: light touch distal, volar fifth digit
  - Motor: interosseous—abduction of the second digit
- Median
  - Sensation: light touch distal, volar second digit
  - Motor: thenar eminence—adduction of the first digit toward the ceiling
- Radial
  - Sensation: light touch to the dorsal web space between the second and third digits
  - Motor: wrist extension, otherwise sensation only in the hand
- Digital
  - Two-point discrimination—2 to 5 mm at the fingertip

Musculoskeletal
- Bony palpation of all digits and joints
- Active range of motion: make a fist; fully extend all digits
- Passive range of motion: passively take all digits and joints through all ranges
- Resistance: test all joints, all ranges with resistance to diagnose partial ligament injuries

Ligamentous
- Flexor digitorum profundus tendon—hold the proximal interphalangeal joint in extension; flex the distal interphalangeal joint against resistance
- Flexor digitorum sublimis tendon—hold the metacarpophalangeal joint in extension; flex the proximal interphalangeal joint against resistance
- Extensor tendons—place the hand palm down; extend the digit with resistance at the nail bed
- Ulnar collateral ligament—adduct the thumb against resistance

Neurologic testing should be performed before local or regional anesthesia. Radial, median, and ulnar nerve function should be individually assessed and the digital nerves interrogated via both light touch and two-point discrimination. Comparison with the unaffected side can be useful. To evaluate for radial neuropathy, the dorsal aspect of the second and third web space is tested for decreased sensation. Proximal limb radial nerve lesions will cause wristdrop. However, the superficial radial nerve, as it courses through the hand, is sensory only. To test for median neuropathy, the distal, palmar surface of the second digit is assessed for decreased sensation. Placing the hand dorsal side down and abducting the fifth digit toward the ceiling tests motor function. Resistance is applied to the thenar eminence, followed by palpation, to test for contraction of the abductor pollicis brevis muscle. To test for ulnar neuropathy, the distal, palmar surface of the fifth digit is assessed for decreased sensation. Challenging the interosseous muscles best tests ulnar motor function. One method is to ask the patient to place the injured hand on a surface with the fifth digit down and the thumb pointing at the ceiling. The patient then abducts the second finger (spreads the fingers) against resistance; weakness of the first interosseous muscle verifies contraction.

Musculoskeletal assessment is targeted at identifying injuries to bones, joints, and ligaments. Bone structures should be palpated thoroughly, as should all joints, to look for signs of pain, laxity, and limited range of motion. Every digit and joint should be put through complete active and passive range of motion. All extensor and flexor tendons should be tested individually. Specific tendon function is evaluated by ranging every joint individually. Extensor tendon function is tested by extending all interphalangeal and metacarpophalangeal (MCP) joints against resistance. Flexor digitorum profundus tendon injury limits flexion at the distal interphalangeal (DIP) joint; its presence is confirmed by holding the proximal interphalangeal (PIP) and MCP joints in extension and flexing the DIP joint against resistance. Flexor digitorum sublimis tendon injury limits flexion at the PIP joint. This injury is confirmed by holding the MCP joint in extension and flexing the PIP joint against resistance. False-negative results occur if all the other digits are not held in complete extension. The uninjured thumb will have complete active range of motion without pain and should be able to oppose the fifth digit. Full flexion to a fist and full extension should be normal.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

FRACTURES OF THE HAND

Metacarpal Bone Fractures

Metacarpal bone fractures cannot be discussed simply as a single group because of the vast differences in inherent mobility and function among them. For each, the tolerance for unreduced angulation varies. The first metacarpal is very mobile and fractures are relatively uncommon. Management includes proper reduction, placement of a thumb spica splint, and follow-up with hand surgery. The second and third metacarpals are the fixed center of the hand, and proper reduction of fractures is important for full return of function. The fourth and fifth metacarpals are more mobile and have greater ability to compensate for angular deformities. Hand surgery consultation is necessary for all metacarpal fractures; for unstable reductions: for irreducible, open, or intraarticular fractures; and for any fracture with rotational malalignment.

Metacarpal base fractures are uncommon and usually of little significance. The exception is at the base of the fifth metacarpal bone, where there can be associated subluxation of the metacarpal-hamate joint. The injured hand should be immobilized in an ulnar gutter splint and scheduled for referral to hand surgery.

Bennett/Reverse Bennett and Rolando Fractures

A Bennett fracture is a fracture of the proximal first metacarpal bone (Fig. 89.1). The classic mechanism is an axial load onto a flexed and adducted thumb. For example, a
injury is most frequently seen when a solid object is forcefully struck with a closed fist. True boxer’s fractures may carry significant morbidity because in addition to being an unstable fracture, the injury often has a rotational component. If allowed to heal in this position, the hand will be deformed and weakened.

ED management consists of an attempt at closed reduction and placement of a dorsal-volar splint. Regardless of the type of splint used, at a minimum the fourth and fifth MCP joints should be splinted at 90 degrees of flexion. Because of the instability of this fracture, all patients should be referred to a hand surgeon and warned of the significant likelihood that the injury will require operative management.

Fig. 89.1  Bennett fracture (arrows). (From Mettler Jr FA. Essentials of radiology. 2nd ed. Philadelphia: Saunders; 2004.)

Fig. 89.2  Boxer’s fracture (arrow). (From Mettler Jr FA. Essentials of radiology. 2nd ed. Philadelphia: Saunders; 2004.)

Proximal and Middle Phalanx Fractures

Proximal and middle phalanx fractures are managed similarly. The degree of instability depends on the nature of the fracture. Transverse and spiral fractures have greater instability than simple fractures do and are therefore more likely to require percutaneous fixation. It is important to keep in mind that rotational deformity cannot be tolerated. When the hand is held in a relaxed fist, the fingers should all point to the scaphoid region. Visible deviation from this plane suggests a rotational deformity of greater than 10%. All nondisplaced proximal and middle phalanx fractures should be splinted in the ED and referred for outpatient follow-up. Rotated, transverse, displaced, or intraarticular fractures should be reduced...
and splinted, and contemporaneous hand surgery consultation should be obtained.

**Distal Phalanx Fractures**
The most common distal phalanx fracture is a tuft fracture, and nail bed injuries are the most common complication of this fracture. There is some controversy regarding the need to repair nail bed injuries; however, most authors recommend performing trephination only for nail bed hematomas involving 30% to 50% or greater of the nail bed surface. When the nail bed is involved, tuft fractures are considered open fractures. Although some physicians prescribe antibiotics empirically, evidence suggests that prophylactic antibiotics are not indicated. Proximal distal phalanx fractures are often unstable and require hand surgeon referral for percutaneous wire placement. An attempt to reduce any rotational deformity or angulation should be made before splinting. Splinting should isolate the DIP joint alone.

**LIGAMENTOUS INJURIES OF THE HAND**

**de Quervain Tenosynovitis**
de Quervain tenosynovitis is an overuse injury of the thumb. The classic example of the mechanism is a fly fisherman who repetitively collects the line after each cast by using the thumb and index finger to grasp the line, thereby resulting in inflammation of the abductor pollicis longus and extensor pollicis brevis tendons. The diagnosis is made clinically, and a positive Finkelstein test is said to be pathognomonic. The Finkelstein test is considered positive when pain is elicited with passive ulnar deviation of a closed fist.

It is important to note that patients with this condition may complain of pain on palpation of the anatomic snuffbox because the aforementioned tendons form the radial border of that structure. If the history is suggestive of a possible scaphoid injury, radiography should be performed and a thumb spica splint applied. Treatment of simple de Quervain tenosynovitis consists of rest, application of ice, and nonsteroidal antiinflammatory drugs (NSAIDs); more severe cases may require splinting to rest the injured joint.

**Gamekeeper’s/Skier’s Thumb**
Gamekeeper’s thumb is also called skier's thumb. The mechanism is hyperextension of an abducted thumb causing injury to the ulnar collateral ligament, and it is often associated with an avulsion fracture (Fig. 89.3). Historically, old-world gamekeepers sustained this injury while dispatching wounded birds during hunts. Today, this injury often occurs when a skier falls while grasping the ski pole.

Physical examination will be remarkable for tenderness at the ulnar collateral ligament, laxity at the MCP joint, and inability to actively oppose the thumb (Fig. 89.4). Most ulnar collateral ligament ruptures occur at the distal attachment. If the injured joint demonstrates 40 degrees of radial angulation during stressing, complete ligament rupture should be assumed. An associated avulsion fracture may be present. Treatment consists of immobilization in a thumb spica splint, NSAIDs, and referral to a hand surgeon for open reduction with internal fixation.

The initial examination may be compromised secondary to pain and spasm. In these cases, the most prudent course of action is immobilization in a thumb spica splint and referral for reevaluation.

**Jersey Finger**
Jersey finger is an injury often associated with tackling sports (Fig. 89.5). The injury itself consists of disruption of the flexor digitorum profundus joint, which is responsible for flexion of the digit at the DIP joint. It occurs when a digit (often the second digit) is forced into extension while actively being flexed, as might occur when grabbing an opponent’s jersey during a tackle.
The patient should be referred to a hand surgeon for follow-up. Most mallet fingers are treated nonoperatively; however, those with large avulsion fracture fragments may require operative management.

**Digital Dislocations**

Dislocation of the DIP joint is a rare injury, but when it does occur, it most commonly dislocates in the dorsal direction after direct force on the finger pad. Relocation is best accomplished after a digital block with traction longitudinally and pressure directing the proximal aspect of the distal phalanx back to correct alignment. After relocation, the entire digit is splinted in extension. Some injuries are nonreducible and require operative repair because the volar plate or profundus tendon (or both) may occupy the joint space. Any indication of joint involvement should prompt referral to a hand surgeon.

PIP joint dislocations result in more complications than do DIP joint dislocations. The complex biomechanics of the joint adds a degree of intricacy that often results in the need for operative repair. The volar plate may be injured with dorsal dislocations, and the lateral collateral ligaments may be injured with ulnar or radial dislocations. It is important to assess any relocated joint for stability to better rule out the potential for ligament or volar plate injury. Patients with an irreducible or unstable joint should be referred to a hand surgeon for operative repair. If stable, the joint should be splinted in 30 degrees of flexion for 2 to 4 weeks.

MCP joint dislocations are seen less commonly than PIP dislocations but have a similar rate of complications. Dislocations may be partial or complete and may involve the volar plate. Care should be taken during the examination to not convert a partial dislocation to a complete dislocation. Injury most commonly occurs as a hyperextension mechanism. With complete dislocations and volar plate involvement, relocation is often impossible because the volar plate may become entrapped in the joint space. For the best chance of relocation, the wrist should be placed in full flexion to relieve all flexor tendon tension and exert longitudinal and volar force. The MCP joint should be splinted in full flexion.

**Extensor Tendon Injuries**

Open wounds on the dorsum of the hand and digits should trigger suspicion for extensor tendon injury. The Verdan extensor tendon injury classification system uses eight anatomic zones to direct treatment (Table 89.1).

Treatment of extensor tendon injuries should usually be coordinated with a hand surgeon. Data on suture repair of partial tendon lacerations are lacking, and current treatment is based on flexor tendon treatment. Conservative treatment of injuries involving less than 50% of a cross-sectional area has been proposed. Injuries to zones I and II occur with axial loading onto a fully extended DIP joint, which forces the DIP joint into flexion and disrupts the distal aspect of the extensor tendon. This creates a mallet injury, as described previously.

Zone III injuries are caused either by axial loading and forced flexion of the PIP joint or by direct trauma to the PIP joint. These injuries should be splinted with the joint in extension, and the patient should be referred to a hand surgeon. With complete disruption of the central slip, the lateral bands slide toward the volar surface of the digit, which causes the extensor tendons to act as flexors. Untreated injuries lead to...
a boutonnière deformity in which the PIP is flexed and the DIP is hyperextended.

Most zone IV injuries are caused by direct trauma. Open injuries may be treated primarily as in zone IV; by definition, no joint involvement is present. Closed injuries should be splinted with extension of the PIP joint. The extensor tendons of the phalanx are broad and flat, which allows easier primary repair.

“Fight bite” must be considered in all patients with zone V ligament injuries. Patients with open injuries should be referred to a hand surgeon for primary repair. Closed injuries can be treated by splinting the MCP joint in extension while allowing free range of motion of the PIP joint.

Zone VI injuries are usually superficial and easily repaired by the EP. Suture material should be strong, such as braided nylon, and the lacerated tendon completely apposed. After closure, the wrist should be splinted in 30 degrees of extension and the MCP joint in 15 degrees of flexion, and the PIP joint should be free. The patient should be referred to a specialist for dynamic splinting.

Zone VII and VIII injuries often involve the extensor retinaculum, and the patient should be scheduled for referral to a hand surgeon for primary closure. The affected tendon often retracts into the forearm, thus complicating the repair. Because of the density of associated anatomic structures, operative survey of the injury to identify additional injuries is indicated.

**Flexor Tendon Injuries**

All patients with open flexor tendon injuries should be referred to a hand surgeon for emergency evaluation (Table 89.2).

However, some knowledge of the nomenclature and prognoses associated with flexor tendon injuries will aid the EP in conversations with both the consultant and the patient.

Repair of complete lacerations within 24 hours is most commonly recommended. Operative repair is usually limited to injuries involving greater than 50% of a cross-sectional area. Injuries involving less than 50% are frequently treated conservatively with splinting. Newer data suggest that conservative management is adequate for injuries occupying less than 75% of a cross-sectional area; however, this decision should be deferred to the consulting hand surgeon. When splinting flexor tendon injuries, the wrist should be placed in 30 degrees of flexion, MCP joint injuries in 70 degrees of flexion, and DIP or PIP joint injuries in 10 degrees of flexion. Classification of flexor tendon injuries is based on anatomic location, treatment, and prognosis. All patients with flexor tendon injuries should be referred to a hand surgeon for operative exploration and repair.

**FRACTURES OF THE WRIST**

Carpal bone fractures can result in significant long-term morbidity and are easily missed during the physical examination. The two most common carpal fractures are fractures of the scaphoid and triquetrum. Scapholunate, perilunate, and lunate dislocations are the most common dislocations.

**Scaphoid Fractures**

The scaphoid is the most commonly injured carpal bone. A high index of suspicion is needed when considering this injury because plain film findings are often subtle or even absent (a dedicated scaphoid view will increase plain film sensitivity). The mechanism of injury is most often a fall onto an outstretched hand.

Morbidity is high with this injury because the bone is anatomically predisposed to avascular necrosis and nonunion. The blood supply to the scaphoid originates from the radial and palmar arteries and flows from distal to proximal. The

Scapholunate Dislocation

Scapholunate dislocation is the most common of these injuries and occurs with the least amount of force. It can be diagnosed on plain film radiography. Scapholunate dislocation results in a classic radiologic finding—the Terry-Thomas sign (Fig. 89.7). Terry-Thomas was a 20th-century British comedian who possessed a noticeable gap between his two front teeth, reminiscent of the wide space (2 mm when measured on an anteroposterior view) seen between the scaphoid and lunate bones when they are dislocated. Stress views accentuate this finding. Additionally, the scaphoid may twist on its axis and cause a ringlike shadow known as the signet ring sign. This artifact is caused by the x-rays traveling longitudinally down the twisted scaphoid, unlike the normal crosswise orientation. Mayfield et al. classified this injury as a stage I injury.6

Perilunate Dislocation

Stage II injury is associated with progressively more force (e.g., an automobile accident versus a slip and fall) and results in perilunate dislocation (Fig. 89.8). Perilunate dislocations may be a difficult concept because there is no “perilunate” bone. Perilunate dislocation is a disruption of the ligamentous structures around (“peri”) the lunate bone. One of these structures is the capitate, which most often dislocates dorsally. Perilunate dislocation may perhaps better be called capitate dislocation; however, perilunate dislocation is actually a more accurate description of the stepwise disease process as outlined by Mayfield et al.6 Dislocation of the capitate can be associated with a scaphoid fracture. The EP should be diligent in assessing for one in the setting of the other. Perilunate dislocation is frequently overlooked despite the classic plain...
film finding of the capitate and the remainder of the distal part of the hand lying dorsal to the lunate on the lateral projection.

**Triquetrum Dislocation**
Stage III injury involves dislocation of the triquetrum but is difficult to differentiate radiographically from stage II perilunate dislocation.

**Lunate Dislocation**
Stage IV injury is defined by the presence of a lunate dislocation. It is a complete disruption of the ligamentous structures of the wrist. In stage I the scaphoid dislocates from the lunate, in stages II and III the capitate and triquetrum dislocate from the lunate, and in stage IV the lunate dislocates from its articulation with the distal end of the radius. The dislocated capitate, which lies dorsal to the lunate, will often collapse onto the distal end of the radius as a result of muscular spasm because the lunate is no longer present to prevent such spasm.

The result is a distal radius and capitate pseudoarticulation, with the lunate lying palmar to the “new” wrist articulation. This is best viewed on a lateral plain film projection and causes the “spilled teacup” sign (Fig. 89.9). When teaching this concept, the author has asked students to imagine a watermelon seed being squeezed between two fingers and then popping forward with force. This is essentially what happens to the lunate as it is “squeezed” by the radius and distal wrist structures, including the capitate, in an extreme hyperextension mechanism. Lunate dislocation often compresses the carpal tunnel and can cause median neuropathy.

Plain film radiography is in general adequate to diagnose carpal bone dislocations, although computed tomography can be helpful in ambiguous cases. The EP may attempt closed reduction; however, many of these injuries are unstable. All injuries should be splinted in a long arm splint and patients should be referred to a hand surgeon. Many of these injuries will require internal fixation.

**BITES TO THE HAND**
Because of the potential for injury and morbidity, all open injuries of the MCP joint should be treated as closed-fist bite wounds, or “fight bites,” until proved otherwise. These often minor-appearing injuries are by definition caused by a clenched fist versus human teeth and are well known for poor outcomes. Potential complications include violation of the joint capsule, extensor tendon injury, and contamination of the deep fascial space. The potential for infection is great because of the poor vascular supply of the extensor tendon and joint capsule. Treatment of these injuries is threefold: surgical decontamination, antibiotics, and dynamic splinting. These injuries are not limited to fist fights and also commonly occur during sporting events.

Delayed manifestations most commonly occur 2 to 3 days after the inciting event and consist of signs and symptoms of local or significantly advanced infection. Any indication of infection or joint space or tendon sheath involvement should prompt referral to a hand surgeon for irrigation and débridement. The timing of initiation of intravenous antibiotics should be determined in consultation with the hand surgeon, who may wish to delay antibiotic treatment until after tissue
for culture has been obtained intraoperatively. Antimicrobial therapy should cover common pathogens found in the human oral and skin flora, including aerobic and anaerobic pathogens. *Staphylococcus aureus* is the most common pathogen, followed by *Streptococcus* species, *Corynebacterium* species, and *Eikenella corrodens*.9

If the signs and symptoms are acute with no indication of fracture, joint space involvement, or extensor tendon injury, antibiotic therapy and local wound care are sufficient. In this nonoperative patient group, wounds should be treated with high-volume irrigation, and they should be left open to heal by secondary intention. The injured hand should be splinted in the position of function, and the patient should be instructed to elevate the affected limb and to return if any evidence of infection is seen.

Prophylactic antibiotics for clenched-fist bite wounds should be initiated for all but the most superficial injuries. Recommended regimens include amoxicillin–clavulanic acid, a combination of penicillin and dicloxacillin, and a combination of penicillin and a first-generation cephalosporin.9

**HIGH-PRESSURE INJECTION INJURIES**

High-pressure injection injuries occur when substances such as paint, oil, grease, solvents, and water are sprayed under high pressure. These substances can penetrate deeply into the soft tissues of the hand and cause inflammation, infection, fibrosis, and severe disability. In one series the rate of amputation approximated 50%, and when patients are initially seen more than 6 hours after the injury, amputations are the rule rather than the exception.10,11 Even a small puncture wound with a history of high-pressure injection should be considered a high-priority emergency.

Historical information, including time since the injury, the material injected, the amount injected, the temperature of the material, and the velocity and pressure of the injection may be helpful in determining the prognosis. For example, the amputation rate is considerably lower with grease injection than with injection of paint or solvent-based material. Thinner and less viscous material is more apt to lead to amputation than with injection of paint or solvent-based material. Thinner and less viscous material is more apt to lead to amputation because of easier spread and a subsequently larger extent of injury.

Plain film radiographs should be obtained to look for subcutaneous air and radiopaque material. The hand should be elevated and maintained in a position of comfort. Parenteral analgesics are often required. Infiltration of anesthetics directly into the area of injury may worsen local inflammation and is therefore contraindicated. All these injuries require immediate consultation with a hand surgeon. Even though several authors recommend prophylactic antibiotics and some suggest systemic corticosteroids to decrease inflammation, few data support either recommendation.

**TREATMENT**

Although individual hand and wrist injuries require specific treatment, several generalizable steps should be taken to optimize management in the ED.

**ANESTHESIA AND ANALGESIA**

The hand is densely innervated to increase tactile discrimination and complex function. Accordingly, hand injuries can be very painful. The decision to manage an injury by infiltration of a local anesthetic, a regional anesthetic technique, oral or parenteral analgesics, or a combination of these approaches will vary. It is worth noting that the hand is highly amenable to regional anesthetic techniques that can be mastered quickly by EPs with a bit of practice. Local and regional anesthesia is discussed in Chapter 10. A number of instructional websites also provide detailed information on these techniques, including a site developed at our institution (see www.mmc.org/em_body.cfm?id=3235).

**TREATMENT OF OPEN WOUNDS**

Unless a plan for intraoperative washout is in place, all open hand and wrist injuries should undergo meticulous irrigation. When performing irrigation, a 60-mL syringe and an 18-gauge angiocatheter or splashguard device will generate the proper irrigation pressure. No study has shown any benefit of wound soaking or the use of antiseptic solution during irrigation. Tap water irrigation has proved to be as safe as irrigation with sterile solutions.7 As a rule, patients with all but the most minor hand injuries should receive prophylactic antibiotics.

**SPLINTING**

For almost every hand and wrist injury, the most important last step is effective splinting. Splinting decreases pain, speeds healing, and reduces the likelihood of fracture displacement.

**RED FLAGS**

**Cautions for Physicians**

Do not cut corners during physical examination of the hand. This will invariably lead to misdiagnosis, mistreatment, and loss of function.

All lacerations involving the extensor surface of the hand are “fight bites” until proved otherwise. Never accept the history at face value when the injury pattern is suspicious.

In patients with a history of high-pressure injection injuries, do not be fooled by a seemingly innocuous skin puncture wound.

Failure to immobilize, failure to consult, and failure to arrange timely follow-up are common avoidable pitfalls in the management of hand and wrist injuries.
Digital injuries can usually be managed with a simple aluminum finger splint. When the injuries are unstable, more complete immobilization of the hand and wrist is recommended. Splinting of the hand should preserve the “position of function”—that is, extension at the wrist, flexion at the MCP joint, and nearly complete extension of the PIP and DIP joints. The objective is to maintain an appropriate amount of tension on ligaments that may shorten over time if relaxed. The position of function can be achieved by asking the patient to hold the hand as though holding a tennis ball and facing it forward.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

The vast majority of hand injuries are amenable to outpatient follow-up. Care pathways should be established between the ED and hand surgeons to ensure that patients are not lost to follow-up when follow-up is vital. A relatively small subset of acute hand injuries will require immediate operative repair (e.g., vascular injuries with compromised perfusion, major crush injuries, amputations) or washout in the operating room (e.g., open fractures and joint injuries, grossly contaminated soft tissue injuries, high-pressure injection injuries, bite wounds at high risk for infection). When in doubt, the EP should not hesitate to obtain phone consultation or call a colleague to the bedside.

Arterial and Venous Trauma and Great Vessel Injuries
Stephen J. Wolf and Margaret M. DiGeronimo

**KEY POINTS**

- Thirty percent of patients with great vessel injury (GVI) die within 6 hours of hospital arrival.
- Thirty percent to 50% of patients with blunt aortic injury have no signs of trauma.
- A normal chest radiograph does not exclude GVI.
- Computed tomographic angiography is the diagnostic test of choice to rule out traumatic aortic injury in hemodynamically stable patients.
- For patients too large for a computed tomography scanner, transesophageal echocardiographic evaluation of the aorta should be considered.
- Medical management of GVI is typically used as a bridge to more definitive operative care.
- β-Adrenergic blockade is instituted before nitroprusside in the medical management of GVI to avoid possible reflex tachycardia.

**EPIDEMIOLOGY**

Few traumatic injuries are more devastating than great vessel injury (GVI). With an average circulating volume of 5 L and a flow rate of up to 4.8 L/min in the circulatory system, it is easy to see why GVI can result in catastrophic outcomes quickly. The true incidence of traumatic aortic injury may never be known; however, according to the National Trauma Data Bank, blunt thoracic aortic injury occurred in 0.3% of trauma patients admitted to the hospital during a 5-year period.¹ When patients survive an initial injury to their great vessels, rapid diagnosis and treatment are imperative to prevent subsequent exsanguination within the next minutes to hours. This highlights the ever-emphasized “golden hour” of trauma resuscitation.

Several contributing factors are important when evaluating potential GVI (Fig. 90.1). Although the mechanism and specific vessel injured are the most important of these factors, significant attention must be paid to the role of concomitant injuries and comorbid conditions on patients’ morbidity and mortality. Unfortunately, on initial evaluation the emergency physician is often lucky to be privy to one, let alone all, of these factors.

The most important branch point for both the likelihood and the type of GVI is a penetrating versus blunt mechanism. Penetrating mechanisms are associated with greater than 90% of great vessel trauma, and any thoracic vascular structure is at risk.² Patients who survive to arrive at the emergency department, particularly if they are not in hemorrhagic shock, have a survival rate that approaches 50%.³

In contrast, blunt traumatic injuries to the great vessels most often affect the aorta, although the innominate artery, pulmonary hilar vessels, and vena cava are also susceptible. Blunt aortic rupture carries an immediate mortality rate of greater than 80% and is responsible for 10% to 15% of motor vehicle accident fatalities.⁴ Because of the high association of blunt ascending aortic injury with fatal cardiac injury, the vast majority of those who survive to hospital evaluation have descending injuries. Of patients who survive until medical evaluation, 30% die within 6 hours and 40% within 24 hours.⁵ Because most of these injuries occur in young healthy males, the overall survival rate is much better than expected given the severity of injury.

Though incompletely understood, it is proposed that blunt aortic injury can result from any combination of shearing forces, rotational forces, increased intraluminal aortic pressure, or a pinching mechanism between the sternum and vertebral column. Given these forces, it is not a surprise that motor vehicle collisions cause the majority of blunt aortic injuries. This association increases with the speed of the accident.⁶ Shearing forces were originally thought to be the highest in frontal-impact accidents, where deceleration forces are the greatest. More recent studies, however, have shown that side-impact accidents are associated with a higher risk for blunt aortic injury. A review of 119 cases of known blunt aortic injury as a result of car accidents in the United Kingdom found that lateral impact direction to the same side was highly associated with aortic injury.⁷ A review of accident data from the United Kingdom and United States in 2004 mirrored these results and found that side impact involving the patient’s side of the vehicle carried a significantly higher risk for aortic injury than did frontal impact.⁸ Although motor vehicle accidents account for the majority of blunt GVI, falls from a height and crushing forces have also been known to cause the disease process.⁹

In part because of difficulty isolating the hilum, injuries to the pulmonary arteries, veins, and thoracic vena cava are associated with mortality rates greater than 60%, regardless of whether they are caused by blunt or penetrating force, although the latter is much more common.¹⁰ Concomitant injuries clearly play a role in the epidemiology, morbidity, and mortality of GVI. One study on blunt thoracic trauma showed that patient with traumatic aortic injury carried a mean injury severity score (ISS) of 40.
whereas patients without vascular injury had a mean ISS of just 16. Another showed that closed head injury was diagnosed in more than half of patients with GVI, with one quarter having intracranial hemorrhage.

Comorbid conditions such as underlying vascular disease, cardiopulmonary disease, and renal insufficiency contribute to the morbidity and mortality associated with GVI. Many disease processes affect a patient’s ability to tolerate the initial and delayed physiologic insults accompanying severe GVI.

**PATHOPHYSIOLOGY**

Knowledge of the vascular anatomy of the great vessels and the particular branch points of the more distal vasculature is important in identifying and potentially preventing morbidity and mortality in the setting of injury. This anatomy can be broken down into arterial, venous, and pulmonary components.

**ARTERIAL SYSTEM**

The systemic arterial great vessels include the ascending aorta, arch, and descending thoracic aorta. The innominate artery is the first branch of the aortic arch and gives rise to the right subclavian and common carotid arteries. The left carotid and then the left subclavian artery are the next two branches. These structures course in close approximation to the clavicle, the first and second ribs, and the brachial plexus. Just distal to the left subclavian takeoff, the descending aorta becomes a more fixed structure in comparison with the arch. The ligamentum arteriosum, a remnant of the ductus arteriosus, and the intercostal arteries tether it to other thoracic structures. This junction, often called the isthmus region, proves to be the most susceptible site for blunt aortic injury as the arch moves in relation to the relatively fixed descending aorta. The spinal arteries branching off the descending aorta are of particular importance because they supply the spinal column. Compromised flow to these small branches as a result of direct injury or vascular clamping plays a significant role in patients’ risk for paraplegia.

The microanatomy of the artery wall, with its intimal, medial, and adventitial layers, is integral in the spectrum of disease. Injuries range from isolated thrombogenic intimal flaps to full-thickness tears with free hemorrhage (Fig. 90.2).

**VENOUS SYSTEM**

The venous components of the great vessel system include the confluence of the subclavian and internal jugular veins, which ultimately combine to form the superior vena cava. The inferior vena cava receives blood from the portal system through the hepatic vein in the retrohepatic region. As a whole, this system is characterized by low pressure and resistance and high flow and compliance, unless tamponade or heart failure is present, which results in increased right-sided pressure. These factors make control of hemorrhage difficult.

**PULMONARY CIRCULATION**

The final component of the great vessel system is the pulmonary circulation. As mentioned earlier, the structures of this system reside in the hilum and are deep in the thorax, thus making them difficult to access. The pulmonary arteries and veins possess mediastinal and intrathoracic portions, which can result in different clinical findings, including mediastinal hematoma or hemothorax.

**PRESENTING SIGNS AND SYMPTOMS**

Traditionally, aortic dissection as a result of nontraumatic causes is believed to be manifested as tearing pain radiating...
The signs and symptoms of GVI often result from its effect on blood flow, which can be secondary to direct vessel injury, traumatic thrombus formation, or vascular compression from surrounding hematoma. Of great concern are clinical signs of hemorrhagic shock such as hypotension, tachycardia, altered mental status, pallor, or diaphoresis. Frequently, hypertension occurs as a result of increased stimulation of sympathetic nerve fibers in close proximity to the aortic arch. Additionally, many of the other signs can be subtle. Dyspnea may result for any number of reasons, such as associated pulmonary injury, hemothorax, hypovolemia with poor tissue oxygenation, or tamponade. Neurologic symptoms can be found in patients with arterial injury involving the carotids or spinal arteries.

Extremity findings of altered transmission or diminished intensity of the pulse pressure wave suggest intravascular volume depletion or, if asymmetric, direct vascular injury. Femoral pulses are important to note, particularly with respect to upper extremity pulses, because change can indicate vascular injury in the descending aorta resulting in a pseudo-coarctation syndrome. Vascular bruits, which result from turbulent blood flow in the arterial system, either over the precordium or in the interscapular region, are heard in up to 30% of patients with aortic injury.

Unfortunately, none of the aforementioned signs and symptoms are sensitive or specific for making the diagnosis of GVI.

GVI should be considered in the differential diagnosis of all patients with thoracoabdominal trauma and an appropriate mechanism of injury. Care must be taken to not exclude the diagnosis solely on the basis of identification of other injuries that might also be contributing to the patient’s clinical findings.

GVI is easily misdiagnosed in hemodynamically stable patients, particularly those without external signs of trauma, because of the nonspecific nature of the initial signs and symptoms of GVI. Penetrating injury in proximity to any of the great vessels mandates consideration of GVI. However, a diagnosis of blunt injury requires assessment of the severity of the causative mechanism (e.g., speed, forces), in combination with the patient’s complaints and findings on physical examination. This pretest probability will ultimately be used by the clinician to guide further diagnostic evaluation for GVI (Box 90.2).

GVI is often associated with either significant multisystem trauma or distinct penetrating injury. In the first situation, the signs and symptoms of GVI are frequently obscured by other distracting injuries, altered mental status, or intubation, thereby necessitating a high level of suspicion and a low threshold for diagnostic testing. In the second situation, diagnostic testing is driven mainly by the pretest probability of GVI (i.e., the location and mechanism of the injury). Figure 90.3 depicts a diagnostic management algorithm for suspected traumatic aortic injury.
The chest radiograph is the initial diagnostic screening tool in patients with history of chest trauma. An upright, posteroanterior view provides the best evaluation of the mediastinum. In patients with concern for spinal injury, a portable supine, anteroposterior view is commonly performed. Note that in the recumbent position the mediastinum may appear artificially widened and hemothorax can be obscured.

Chest radiography is not diagnostic of GVI; rather, it is used to identify any of the multiple findings suggestive of aortic injury. **Box 90.3** reviews the classic findings on chest
isolated intimal tears, such that it approaches 100%. More recent studies focusing on the use of 64-slice multidetector CT have added to the evidence that sensitivity and specificity approaching 100% make this the preferred imaging modality. An additional benefit is its ability to identify concomitant or alternative injuries. Limitations of CTA of the chest for GVI include poor delineation of nonaortic vascular injuries and the need for relative hemodynamic stability in the patient.

Because of the ease and accuracy of CTA, use of the traditional “gold standard” for traumatic aortic injury, aortography, has markedly diminished over the past decade. In fact, newer studies are questioning the role of aortography even in the setting of equivocal CT findings. Several studies have shown that catheter angiography following equivocal findings on CTA is unlikely to reveal GVI, which has led some authors to suggest that patients be monitored clinically with or without repeated cross-sectional imaging, thus obviating the need for aortography.

Transesophageal echocardiography (TEE) is another modality that can be used to evaluate aortic injury. Availability reduces its usefulness in the emergency setting, but it should be considered for patients who are too unstable to leave the department or when body habitus prohibits the use of a CT scanner. Its use is contraindicated in patients with unstable cervical spine injuries or suspected esophageal trauma. TEE has similar sensitivity as CTA of the chest in the evaluation of traumatic aortic injury.

**TREATMENT**

**INITIAL INTERVENTIONS AND PROCEDURES**

When great vessel trauma is suspected, adequate vascular access should be obtained immediately. Although two large-bore peripheral intravenous lines are frequently cited as being sufficient for trauma patients, the benefits of central venous pressure monitoring and rapid large-volume resuscitation may necessitate central access. Ideally, the suspected vascular injury should not be affected by the site chosen for central venipuncture. For example, with penetrating injury involving the descending aorta, concomitant vena cava injury is possible; solely femoral or lower extremity access would therefore not be optimal. Unfortunately, in the setting of undifferentiated thoracic trauma, the options may be limited.

Many of the initial emergency resuscitative efforts needed in patients with great vessel trauma are dictated by hemodynamic instability. Patients with traumatic cardiac arrest or extreme hemodynamic compromise unresponsive to crystalloid and packed red blood cell transfusions are candidates for emergency department resuscitative thoracotomy. This procedure is usually performed without knowledge of the exact injury. Consequently, it must be executed methodically such that all potential lifesaving interventions are performed. Injuries to the ascending aorta or aortic arch mandate manual pressure for control of hemorrhage, whereas injuries to the descending aorta require cross-clamping above the site of injury until stability and repair can be achieved. Injuries to aortic arch branch vessels may be tempered by packing the apex of the injured hemithorax. Suspected injury to the right hemithorax requires extension of the thoracotomy into the right side of the chest. Right-sided thoracotomy could be
considered in the rare incidence of an isolated transthoracic right-sided penetrating injury.

Identification of pulmonary hilar injury or excessive bleeding from deep in the thorax, despite aortic cross-clamping, suggests the need to clamp the affected pulmonary hilum. This is achieved either through manual compression or with a vascular clamp. The goal of emergency department thoracotomy is to achieve enough clinical stabilization to allow definitive operative repair.

**DEFINITIVE TREATMENT**

Definitive treatment of GVI is usually surgical or endovascular repair. With mortality rates associated with these injuries increasing at an estimated rate of 1% per hour over the 48 hours after arrival at the hospital, expediting time to intervention is imperative. Surgical techniques usually include clamping and aortic reconstruction with or without vascular bypass. In part because of the need for vascular clamping, paraplegia can be a complication of repair in up to 4% to 20% of patients. Although cross-clamp times are not thought to directly correlate with the incidence of paraplegia, keeping times under 30 minutes is believed to be beneficial.3,17 More recently, endovascular stenting has become an alternative to open surgical repair.18,19 Potential benefits of endovascular repair include a less invasive approach and avoidance of aortic cross-clamping (which may lead to lower rates of paraplegia), cardiopulmonary bypass, and systemic heparinization. Endovascular stenting can be performed in less time and in patients too unstable for operative intervention. A meta-analysis of endovascular versus open repair published in 2008 showed lower mortality rates and lower risk for paraplegia with endovascular repair. It is thought that the mortality benefit relates to the less invasive approach and lack of systemic heparinization given that the majority of these patients have concomitant intraabdominal, intracerebral, or intrapulmonary injuries at high risk for bleeding complications.20

Before surgical or endovascular intervention, medical management is critical and should include pharmacologic reduction of wall tension and shearing forces to prevent propagation of intimal tears and minimize the risk for subsequent in-hospital catastrophic rupture of a contained hemorrhage. One study demonstrated that by starting pharmacologic management as soon as possible, even before a confirmative diagnostic test when suspicion is high enough, morbidity and mortality were reduced significantly.13

Beta-blockers are the first-line medication for reducing wall stress and controlling the heart rate. Esmolol is ideal because of its rapid onset of action and short half-life, which makes it easy to titrate in a continuous infusion. When further blood pressure control is desired, vasodilators such as nitroprusside can be added after beta-blockade has been established. Because of the potential for reflex tachycardia, which increases shearing forces, caution should be exercised when using nitroprusside alone.12,21 Table 90.1 lists drug dosages for esmolol and nitroprusside.

A second but controversial intervention is permissive hypovolemia, in which blood pressure is controlled by limiting fluid administration. Lower systolic pressures of 60 to 90 mm Hg are thought to decrease the risk for clot rupture and minimize the shear force on traumatized vessels. Patients often have associated pulmonary contusions, which strengthens the rationale for limiting fluid administration before operative intervention.22,23 Animal studies using permissive hypovolemia have shown consistent benefit, whereas human trials have been few and the results conflicting.

Two other interventions that are often used during global resuscitation require special consideration in the setting of GVI. Central line access provides important information during resuscitative efforts; however, caution must be taken to avoid further vessel damage by choosing a site farthest from the suspected vessel injury. Similar caution must be undertaken when considering chest tube placement to resolve hemothorax. This action may disrupt the containment of a great vessel hemorrhage with the catastrophic result of exsanguination of the patient.

Ideally, immediate surgical or endovascular repair of GVI has been recommended. However, recent studies have looked at delayed repair, particularly in patients with significant associated injuries or hemodynamic instability. Repair of great vessels has been delayed as long as 6 to 8 months.25 One prospective multicenter study in 2009 examined delayed repair of blunt traumatic aortic injury in stable patients and found significant survival benefits in all patient groups, particularly striking in those with associated injuries.26 Delayed repair is not routinely performed yet but may become more prevalent as further studies focus on this approach.

If a patient survives the first 24 hours without rupture, a stable pseudoaneurysm may develop. In such cases nonoperative management, including close monitoring and pharmacologic control of blood pressure, may be considered.

Acute Compartment Syndromes

David A. Peak

Acute Compartment Syndromes (Box 91.1). Myofascial causes include long-bone fracture, vascular injury, reperfusion after ischemia, burns, prolonged positioning from a drug overdose or operating procedures, compression from tight casts and dressings (including military antishock trousers), overexertion, hemorrhage, injection of fluid into the compartment, massive intravenous fluid infusions, envenomations, hypothyroidism, and rhabdomyolysis. CS has also been reported with deep vein thrombosis and ruptured Baker cysts (see Box 91.1). High-risk patients with an altered sensorium may be unable to provide an appropriate history. CS usually develops hours after the inciting event and rarely more than 48 hours after the inciting event.

Clinicians must remain vigilant and retain a high index of suspicion to avoid missing the diagnosis. Patients with a high mechanism of trauma and an altered sensorium should be examined carefully. The physical examination should focus on evidence of trauma and gross deformity, as well as assessment of neurovascular abnormalities. Comparing one extremity with the unaffected side is often very useful. Serial examinations are often required.

Acute CS is a clinical diagnosis. The essential clinical feature in a conscious patient is severe pain out of proportion to the injury that is aggravated by active or passive stretching of the muscles of the affected compartment or by palpation of the affected compartment. In early cases, pain is the only abnormality. Increasing pain or pain refractory to analgesics suggests the diagnosis. Severe pain while at rest or without any movement should raise suspicion for acute CS. Increasing need for analgesia or increased analgesic dosing is common. The diagnosis is far more challenging in patients who cannot communicate (i.e., altered mental status).

The natural progression of untreated acute CS is severe pain, decreased sensation, decreased strength, and eventual paralysis of the affected limb. With the exception of pain and paresthesia, the traditional five P’s (pain, paresthesia, pallor, pulselessness, poikilothermia) are misleading and more relevant for arterial injury or occlusion. Patients with severe CS, even those with extensive myonecrosis, may have palpable pulses and preserved capillary refill until late in the course. Pulse deficits should raise suspicion for a vascular injury alone or coexisting with acute CS. Decreased two-point discrimination is consistently the earliest physical abnormality and can help differentiate which compartments are affected. Correlation has also been reported between decreasing vibratory sense (256 cycles per second) and increasing compartment pressure.

**KEY POINTS**

- Severe pain out of proportion to the clinical situation is the main feature of acute compartment syndrome and often the only early finding.
- Early diagnosis, consultation, and treatment are the keys to a good outcome.

**EPIDEMIOLOGY**

The true incidence of acute compartment syndrome (CS) varies with the inciting event. Almost half of all cases of CS are related to tibia fractures. The incidence of CS with tibia fractures is 1.2% with closed fractures, 6% with open fractures, and as high as 19% with concomitant vascular injury.1,2 The forearm is the second leading site. CS can occur in any contained compartment.

**PATHOPHYSIOLOGY**

CS is a condition of impaired microcirculatory perfusion related to increased interstitial pressure within a closed compartment. CS begins when increased pressure as a result of increased volume within or external pressure compromises microcirculatory perfusion within that space. Once autoregulatory reductions in the arteriovenous gradient are overwhelmed, interstitial pressure will rise above capillary perfusion pressure (normally between 20 and 30 mm Hg in a normotensive patient for most compartments), and tissue ischemia will occur.2 CS is characterized by a self-propagating cycle of impaired perfusion resulting in ischemia, release of osmotically active particles, and edema, which further increase interstitial pressure and diminished perfusion (Fig. 91.1).

**PRESENTING SIGNS AND SYMPTOMS**

CS should be on the working list of “worst-case” diagnoses for every patient with musculoskeletal pain. CS may result from either externally applied compressive force or internally expanding force, and a suggestive history should be elicited (Box 91.1). Myofascial causes include long-bone fracture, vascular injury, reperfusion after ischemia, burns, prolonged positioning from a drug overdose or operating procedures, compression from tight casts and dressings (including military antishock trousers), overexertion, hemorrhage, injection of fluid into the compartment, massive intravenous fluid infusions, envenomations, hypothyroidism, and rhabdomyolysis. CS has also been reported with deep vein thrombosis and ruptured Baker cysts (see Box 91.1). High-risk patients with an altered sensorium may be unable to provide an appropriate history. CS usually develops hours after the inciting event and rarely more than 48 hours after the inciting event.

Clinicians must remain vigilant and retain a high index of suspicion to avoid missing the diagnosis. Patients with a high mechanism of trauma and an altered sensorium should be examined carefully. The physical examination should focus on evidence of trauma and gross deformity, as well as assessment of neurovascular abnormalities. Comparing one extremity with the unaffected side is often very useful. Serial examinations are often required.

Acute CS is a clinical diagnosis. The essential clinical feature in a conscious patient is severe pain out of proportion to the injury that is aggravated by active or passive stretching of the muscles of the affected compartment or by palpation of the affected compartment. In early cases, pain is the only abnormality. Increasing pain or pain refractory to analgesics suggests the diagnosis. Severe pain while at rest or without any movement should raise suspicion for acute CS. Increasing need for analgesia or increased analgesic dosing is common. The diagnosis is far more challenging in patients who cannot communicate (i.e., altered mental status).

The natural progression of untreated acute CS is severe pain, decreased sensation, decreased strength, and eventual paralysis of the affected limb. With the exception of pain and paresthesia, the traditional five P’s (pain, paresthesia, pallor, pulselessness, poikilothermia) are misleading and more relevant for arterial injury or occlusion. Patients with severe CS, even those with extensive myonecrosis, may have palpable pulses and preserved capillary refill until late in the course. Pulse deficits should raise suspicion for a vascular injury alone or coexisting with acute CS. Decreased two-point discrimination is consistently the earliest physical abnormality and can help differentiate which compartments are affected. Correlation has also been reported between decreasing vibratory sense (256 cycles per second) and increasing compartment pressure.
The differential diagnosis includes any disorder that can cause musculoskeletal pain, including fracture, contusions, and hematomas; however, pain from other causes generally diminishes after the inciting event, whereas in acute CS, the pain generally increases even while the patient is at rest. Arterial injury will be manifested as abnormal pulses at the onset. Crush injury shares some overlapping features with CS, but the primary pathophysiology is thought to be direct tissue injury, and fasciotomy is rarely indicated.

The diagnosis cannot be made with radiographic imaging. However, because the differential diagnosis for acute CS includes fracture or dislocation and because the risk for CS increases with fracture, radiographic imaging may be useful. Computed tomography or ultrasound is rarely indicated but may be helpful in establishing the cause of the CS (i.e., fracture, hematoma).
compartment measurements that do not reach the threshold for emergency surgical decompression should be admitted for observation. Patients with suspected impending acute CS should be admitted for serial examinations and observation. The prognosis depends on early diagnosis and treatment. Severe disability, amputation, and even death may occur when the diagnosis is delayed or missed. Pitfalls include failure to make the diagnosis or consult surgery when indicated.

**DOCUMENTATION**

*History:* A careful history will include the mechanism, timing, history of paresthesia or weakness, medical conditions that may impair oxygenation or perfusion, coagulopathy or anticoagulation therapy, intravenous drug use, increasing pain, and pain with active or passive movement.

*Physical examination:* Including neurovascular signs, compartment palpation, discoloration, masses, range of motion.

*Medical decision making:* Reasons to pursue or not pursue work-up or consultation.

*Patient teaching:* Patients with significant extremity pain but who do not have clinical evidence of acute compartment syndrome should be counseled to avoid activity, maintain the extremity at the level of the heart, and return if any increase in pain occurs.

**SPECIAL CIRCUMSTANCES**

**ACUTE ORBITAL COMPARTMENT SYNDROME**

Acute orbital CS is considered a rare complication of facial trauma (usually blunt) or surgery. The globe and retrobulbar contents are encased in a continuous cone-shaped fascial envelope that is bound on all sides by seven rigid bony walls, except anteriorly, where the orbital septum and eyelids form another, fairly inflexible boundary. The medial and lateral canthal tendons attach the eyelids to the orbital rim and limit forward movement of the globe.

The orbit may compensate for small increases in orbital volume by forward movement of the globe and prolapse of fat, followed immediately by a rapid rise in orbital tissue pressure. The orbit therefore follows pressure-volume dynamics with a pathophysiology akin to that with CS in other compartments: increased tissue pressure in an enclosed space is associated with decreased perfusion. Ischemia ensues when orbital pressure exceeds central retinal artery pressure.

Symptoms and signs include eye pain, visual loss, proptosis, reduction of ocular mobility, diplopia, increased intraocular pressure, chemosis, and (late) afferent pupillary defect. Diagnosis requires high clinical suspicion and may require serial examinations, including visual acuity tests.

Suspected acute orbital CS with a decrease in vision, loss of vision with increasing intraocular pressure, or high suspicion in a comatose patient requires treatment to prevent permanent blindness. Computed tomography or magnetic resonance imaging is not necessary to make the diagnosis. Irreversible optic nerve pathology may occur with as little as 2 hours of ischemia.

Medical therapy and ophthalmologic consultation should proceed promptly, before the diagnosis is established. Osmotic agents and carbonic anhydrase inhibitors are part of established protocols at many centers. Most experts also recommend high-dose steroid therapy. Less agreement exists about the use of topical beta-blockers and multiple osmotic agents.

The emergency procedure of choice for loss of visual acuity associated with acute orbital CS is lateral canthotomy and cantholysis of the canthal ligaments (Box 91.3; Figs. 91.2 and 91.3; also see the Tips and Tricks box). Primary indications for lateral canthotomy and cantholysis include intraocular pressure greater than 40 mm Hg with visual loss.

**Box 91.2 Management of Acute Compartment Syndrome**

- Consult surgery.
- Maintain the affected area at the level of the heart.
- Reverse hypoperfusion/hypotension.
- Maximize oxygenation/administer supplemental oxygen.
- Correct coagulopathy if present.
- Correct anemia if present.
- Modify the cast, splint, or dressing if this is the precipitant of the syndrome.
- Order antivenom if envenomation is the cause of the syndrome.

**Box 91.3 Primary Indications for Lateral Canthotomy/Cantholysis**

Suspected orbital compartment syndrome with one or both of the following:

- Decreasing vision
- Increasing intraocular pressure

When vision cannot be assessed and clinical suspicion is high (e.g., a comatose patient).

**Fig. 91.2 Lateral canthotomy.**
and proptosis, which may be used as a criterion for an unconscious patients whose visual acuity cannot be determined. Secondary criteria include an afferent pupillary defect, ophthalmoplegia, cherry-red macula, optic nerve head pallor, and severe pain, but these signs are all considered less sensitive or very late.

A contraindication to lateral canthotomy is a suspected ruptured globe. In an experimental model, lateral canthotomy/cantholysis produced a mean decrease in intraocular pressure of 30.4 mm Hg.\(^8\) Emergency department personnel should be familiar with and able to perform this procedure in the event that emergency ophthalmology consultation is delayed.

**ABDOMINAL COMPARTMENT SYNDROME**

Abdominal CS is a sudden increase in intraabdominal pressure that results in dysfunction of the respiratory, cardiovascular, and renal systems.\(^10\) Normal intraabdominal pressure is 0 to 5 mm Hg. Acute abdominal CS was defined by the 2004 International Abdominal Compartment Syndrome Consensus Definitions Conference Committee as sustained intraabdominal pressure greater than 20 mm Hg that is associated with new organ dysfunction or failure. It is most common after abdominal surgical procedures but can also occur with peritonitis, intraabdominal abscesses, intestinal obstructions, ruptured abdominal aneurysms, acute pancreatitis, intraperitoneal or retroperitoneal hemorrhage, ascites, ovarian tumors, and massive edema following resuscitation.

The diagnosis depends on high clinical suspicion combined with the presence of clinical parameters, including intraabdominal pressure elevated to greater than 20 to 25 mm Hg (most commonly assessed with a device used to measure bladder pressure), a distended abdomen, elevated peak airway pressure, large intravenous fluid requirements, elevated central venous pressure, oliguria or anuria not responding to volume repletion, decreased cardiac output, hypoxemia, hypercapnia, acidosis, and a wide pulse pressure.

Treatment consists of rapid surgical decompression, as well as restoration of intravascular volume, maximization of oxygen delivery, and correction of acidosis and coagulopathies. Mortality associated with abdominal CS can exceed 50%.

**CHRONIC COMPARTMENT SYNDROME**

Chronic CS was first described in 1956 and initially thought to be a form of shin splints (anterior tibial enthesitis). Chronic CS (also known as exertional or recurrent CS) is not a surgical emergency. It is commonly reproducible with a certain specific exercise or exercise distance. Symptoms subside with termination of the exercise and are minimal with normal daily exercise. When suspected, patients should be advised to rest and be referred to an orthopedic or sports medicine specialist.

physician complacence in the evaluation of a presumably benign disorder.

Conversely, LBP can be incapacitating, and the patient may perceive the problem as a harbinger of death or disability, regardless of the cause. Patient expectations of a specific diagnosis of the pain source and a complete cure are rarely met and are probably unrealistic. Psychologic, social, and economic factors play a role in the natural history of many pain-related conditions, including progression of LBP from an acute to a chronic condition. LBP often becomes a chronic condition subject to exacerbations, akin to asthma and diabetes mellitus. These issues combine to make LBP a source of frustration for patients and physicians alike.

PATHOPHYSIOLOGY

LBP is a symptom complex caused by a variety of diseases and anatomic abnormalities. Multiple potential sources of pain intrinsic to the spinal column (joints between vertebrae, sacroiliac joint, intervertebral disks, vertebral bones, periosteum, ligaments, meninges, paraspinal muscles, fascia, blood vessels, and nerves) have been implicated. Additionally, a number of visceral structures may be a source of pain referred to the low back region.

LBP is often classified as specific or nonspecific, mechanical or nonmechanical, or primary or secondary or is classified on the basis of presumed etiology (structural, neoplastic, referred pain or visceral, infectious, inflammatory, or metabolic). All these classification systems recognize that in the majority of cases a specific pathoanatomic diagnosis cannot be assigned. Indeed, clear correlation between a specific anatomic abnormality and pain is rarely established in patients, and proposed mechanisms of pain in the medical literature have been fraught with controversy. For example, many asymptomatic subjects have evidence of bulging, prolapsed, or herniated intervertebral disks.

PRESENTING SIGNS AND SYMPTOMS

CLASSIC SYMPTOMS

In general, patients complain of pain described as a dull ache that is mild to moderate in intensity. Its onset is frequently attributed by patients to lifting, bending, or twisting activities and may be abrupt. Movement tends to exacerbate the pain,
whereas rest, especially recumbency, minimizes or relieves it. The pain can be midline, unilateral, or bilateral and may radiate to the buttocks or thighs. Because of the recurrent nature of LBP, many patients have experienced similar pain in the past.

**TYPICAL VARIATIONS**

Pain that is not relieved or worsens when the patient lies down or pain that awakens the patient from sleep is concerning because it may portend a systemic source of the pain. Pain that is unremitting for more than 4 to 6 weeks or that continues despite rest and adequate analgesia often has a specific cause. LBP can occur alone or as one of a constellation of associated symptoms that are frequently more important than the pain itself in determining an accurate diagnosis and treatment plan. Certain symptoms, comorbid diseases, medication use, and signs are “red flags” in that they point to specific, often serious diagnoses.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Nonmechanical causes must be distinguished from mechanical causes of LBP. The key to such distinction rests on eliminating systemic (infectious, neoplastic, metabolic, or inflammatory) and visceral causes. Figure 92.1 shows one diagnostic approach, and Box 92.1 lists the differential diagnosis for LBP.

Specific causes of LBP are shown in Table 92.1, together with red flag signs or symptoms suggesting these diagnoses. When the history and physical examination suggest a nonmechanical cause of LBP, appropriate diagnostic testing or specialty consultation (or both) is necessary to confirm or rule out the suspected specific cause or causes.

Visceral and systemic causes of LBP, though rarely found in most ambulatory care settings, must be addressed. Visceral sources of referred pain that cause LBP can result from a variety of vascular, pelvic, renal, and gastrointestinal pathology. Pain from aortic dissection, for example, can be referred to the back. Similarly, retroperitoneal pathology of any source, including hematomas and metastatic disease, can cause LBP. Patients with pain from these sources may or may not have other clues to the source of their pain. Clues to the diagnosis of aortic dissection may include a diminished femoral pulse or mottling of a leg. Because testicular cancer metastasizes to the retroperitoneum, genitourinary examination might identify the pathology.

A retroperitoneal hematoma may be heralded only by tachycardia or, rarely, by hypotension from blood loss. More commonly, warfarin or an antiplatelet agent may be a contributing factor. Any of these clues may be subtle but may also be the only evidence of an important diagnosis.

Systemic causes of LBP are disease processes that involve the structures of the spinal column, including cancer, infection, inflammation, and degenerative processes. Cancer (with metastatic or primary tumor invasion of the spinal column) typically occurs in those older than 50 years. Weight loss, pain with bed rest, and failure of therapy (with pain lasting a month or longer) are frequent symptoms. Back pain in any patient with a history of cancer should be considered to be due to a cancerous lesion of the spine until ruled out. Infections involving the spine (spinal epidural abscess [SEA], osteomyelitis, and diskitis) are rare. Prudent suspicion, deliberate consideration, and attention to patient risks are the most important ways to facilitate successful diagnosis. Patients with sickle cell disease are predisposed to Salmonella osteomyelitis. Patients with immunosuppression, chronic corticosteroid therapy, injection drug use, and recent bacterial infections (cellulitis, pneumonia, urinary tract infection) are at increased risk for SEA, osteomyelitis, and diskitis. Patients with SEA may have isolated back pain, spotty neurologic changes that do not fit a discrete distribution, or pain that mimics sciatica.

Inflammatory arthritides such as ankylosing spondylitis can cause LBP but are frequently associated with other arthritic and systemic symptoms. Patients with these diseases usually report pain that worsens with lying down, as well as morning stiffness that gradually improves with activity. The pain is usually chronic, with a duration of 3 or more months, and is of gradual onset. Ankylosing spondylitis is most common in young men, with symptoms usually appearing before the age of 40.

Once possible visceral and systemic causes of the patient’s symptoms have been excluded, the focus should be shifted to determine whether neurologic compromise has occurred. Additionally, diagnoses that may lead to spinal instability (fracture and spondylothesis) should be considered.

LBP can be associated with leg pain secondary to radiating pain, but other causes include sciatica (or lumbosacral radiculopathy) with pain radiating from the back to the buttock and posterior or lateral aspect of the leg. Sciatica is frequently caused by lumbar degenerative disk disease. True sciatica usually causes pain below the knee; at least 95% of degenerative disks in the lumbar spine occur at the L4-L5 and L5-S1 vertebral levels. For this reason, the neurologic examination should be focused on both sensory and motor testing of the
lumbosacral nerve roots. Table 92.2 details the motor, sensory, and reflex test components of the neurologic examination of patients with LBP. Note that functional strength testing is more likely than simple motor testing to detect subtle muscle weakness.

Passive straight leg raise (SLR) testing appears to help in the diagnosis of sciatica by stretching the sciatic nerve. A positive ipsilateral SLR test (which results in pain below the knee when the leg to which LBP radiates is raised higher than 30 to 60 degrees with the patient supine) is sensitive but not specific for sciatica, whereas a positive crossed SLR test (in which pain in the affected leg is provoked or worsened when the contralateral leg is raised) is specific but insensitive. A negative SLR test may be of greater value because patients with this finding generally have good long-term outcomes.

Spinal stenosis can result from a variety of processes that impinge on the spinal cord (usually hypertrophy of the ligamentum flavum) and cause pseudoclaudication—back and leg pain with walking and extension of the spine that improves with sitting and lumbar flexion. Most cases occur in patients 55 years or older; they usually report an insidious onset of symptoms.

Cauda equina syndrome (CES) results from compression of the conus medullaris of the spinal cord or the nerve roots that make up the cauda equina. It is typically caused by a large central disk herniation but can also be due to other space-occupying lesions such as spinal stenosis, tumor, SEA, and hematoma. The most consistent findings in patients with CES are LBP, urinary symptoms, and sacral and perineal (“saddle”) paresthesias. Bilateral sciatica is also a concerning symptom. Central disk herniations may not cause sciatica, and back pain may be a minor component of the patient's symptoms. The presence of urinary retention has good sensitivity and specificity for CES. Magnetic resonance imaging (MRI) is diagnostic and usually shows severe spinal canal impingement by a disk.

Expeditious diagnosis and therapy may help maximize the long-term outcome (in terms of pain and disordered bladder, bowel, and sexual function) in these patients. Despite some controversy regarding the role of impairments already present at diagnosis, there appears to be some improvement in the

*Figures in parentheses indicate the estimated percentages of patients with these conditions among all adult patients with low back pain in primary care. Diagnoses shown in italics are often associated with neurogenic leg pain. Percentages may vary substantially according to demographic characteristics or referral patterns in a practice. For example, spinal stenosis and osteoporosis are more common in geriatric patients, spinal infection in injection drug users, and so forth.

†The term mechanical is used here to designate an anatomic or functional abnormality without underlying malignant, neoplastic, or inflammatory disease. Approximately 2% of cases of mechanical lower back or leg pain are accounted for by spondylolysis, internal disk disruption, or discogenic low back pain and presumed instability.

Strain and sprain are nonspecific terms with no pathoanatomic confirmation. Nonmechanical lower back pain or idiopathic low back pain may be a preferable term.

§Spondylolysis is as common in asymptomatic persons as in those with low back pain; thus its role in causing low back pain remains ambiguous.

†Internal disk disruption is diagnosed by provocative diskography (injection of contrast material into a degenerated disk with assessment of pain at the time of injection). However, diskography often causes pain in asymptomatic adults, and the condition in many patients with positive diskogram findings improves spontaneously. Thus the clinical importance and appropriate management of this condition remain unclear. The term diskogenic lower back pain is used more or less synonymously with the term internal disk disruption.

Presumed instability is loosely defined as greater than 10 degrees of angulation or 4 mm of vertebral displacement on lateral flexion and extension radiographs. However, the diagnostic criteria, natural history, and surgical indications remain controversial.

**Scheuermann disease and Paget disease of bone probably account for less than 0.01% of nonmechanical spinal conditions.**

---

outcome of CES if decompression is performed within 48 hours of arrival in the emergency department (ED)\textsuperscript{8}.

LBP without a systemic or visceral cause and without neurologic compromise may nevertheless occur as a result of a specific mechanical cause, usually involving the spinal column itself. Lumbar fractures generally result from significant trauma (e.g., falls from heights, external trauma) but can be caused by minor trauma in older patients, in patients receiving chronic corticosteroid therapy, and in persons at risk for pathologic fractures (e.g., because of bony metastases or osteoporosis of the spine).

A history of trauma and bone tenderness (to palpation or percussion) suggests fracture as a possible cause of LBP. Stress fractures of the sacrum and lumbar spine and insufficiency fractures of the sacrum are other causes of LBP to which athletes (especially young athletes) and older patients (especially women), respectively, are predisposed.

Spondylolisthesis, or slippage of one vertebral body relative to an adjacent vertebral body, is a specific mechanical cause of LBP that can lead to progressive instability. It occurs as a result of a defect in the pars interarticularis from either a fracture or spondylolysis, which can be congenital or degenerative in etiology. Spondylolisthesis can also lead to degenerative disk disease and osteophyte development. Instability causes symptoms similar to those of spinal stenosis.

*Age younger than 20 years is associated with increased risk for spondylolysis, spondylolisthesis, and stress fractures; age older than 50 years suggests increased risk for cancer and compression fractures.

†Unexplained weight loss is defined as more than 10 lb over the preceding 6 months.

‡Most commonly caused by a herniated lumbar disk or lumbar spinal stenosis rather than malignancy.

§Significant trauma is a fall from a height or external trauma such as a motor vehicle accident.

\textsuperscript{1}Substance abuse can increase the risk for fracture through higher rates of trauma. Alcohol abuse can also increase the risk for fracture as a result of decreasing bone density.

*Sharp/dull or pinprick.
Children have back pain at higher rates than previously appreciated and are at higher risk for spondyloysis and spondylolisthesis, especially adolescent and teenage athletes. A one-legged hyperextension test may help diagnose these conditions. Bone scans using single-photon emission computed tomography may be the most appropriate initial test, assuming that the findings on plain radiography are normal.9

Finally, nonspecific mechanical causes of LBP may be the root of patients’ symptoms when possible systemic and visceral sources have been ruled out and no signs of instability or neurologic compromise are present. Nonspecific LBP syndromes have been called lumbago, lumbar sprain or strain, idiopathic LBP, myofascial strain, and a variety of other names. These patients tend to be most comfortable at rest, and their symptoms worsen with activity and movement. They do not have red flags (that suggest specific musculoskeletal, systemic, or visceral sources of their pain) in their history and physical examination, nor do they have signs or symptoms of neurologic compromise.

The Waddell signs have been promoted as tools to help demonstrate a “nonorganic” cause of patients’ symptoms, but they are mainly useful for predicting patients at risk for prolonged recovery from LBP.10 Waddell signs may also point to a diagnosis of depression or another psychoneurosis.

**DIAGNOSTIC TESTING**

Plain films of the lumbosacral spine, rectal examination, postvoid residual bladder volume, the erythrocyte sedimentation rate, and MRI are useful diagnostic adjuncts in the ED (Table 92.3). Other studies such as myelography (plain or computed tomographic [CT]), electromyography, and diskography should be obtained at the discretion of consultants.

If an abdominal aortic aneurysm or dissection is a consideration in the diagnosis, it must be ruled out by an appropriate imaging study, either ultrasound or CT scanning. Urinalysis (and culture as indicated) is recommended for patients in whom urinary tract infection or renal disease is likely. Other specific conditions causing LBP may be diagnosed with appropriate tests as indicated by their differential diagnosis.

**TREATMENT**

**PREHOSPITAL MANAGEMENT**

Prehospital treatment of LBP consists of immobilization of patients who may have spinal instability or a neurologic deficit, resuscitation of those with systemic or visceral causes of their symptoms, and analgesia.

**HOSPITAL MANAGEMENT**

ED diagnostic and treatment priorities are shown in the Priority Actions box. Early institution of intravenous corticosteroids such as dexamethasone (for tumors or disks causing cord or conus medullaris compression) or intravenous antibiotics (for osteomyelitis, SEA, and other infectious processes) should be considered if these diagnoses are likely.

CES, Cauda equina syndrome; SEA, spinal epidural abscess.

Placement of a Foley catheter may provide improved comfort and convenience in nonambulatory patients, and decompression of the distended bladder in patients with neurogenic bladder may improve later voiding function.

Nonspecific LBP is usually self-limited and of short duration: about 60% of cases will resolve within 1 week and 90% within 2 to 6 weeks. Treatment is conservative. Acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) are first-line analgesics; they are usually prescribed for all patients who do not have contraindications.11 Patients should be instructed to use NSAIDs routinely because administration only as needed does not seem to be as effective. Narcotic administration is restricted to patients with severe pain and only for short courses. Narcotics are not more beneficial than
other medications for acute or subacute LBP and may lead to higher rates of chronic pain.\textsuperscript{12} See Table 92.4 for other treatment modalities.

Patients frequently prefer “alternative” modes of therapy (e.g., chiropractic or osteopathic spinal manipulation, acupuncture, massage, magnets) over traditional allopathic approaches. In most cases there are neither proven benefits nor drawbacks to these therapies\textsuperscript{13}; however, patients will often use them regardless of physician recommendations. Risk for CES may be increased following manipulation in patients with disk disease, tumors, or other specific diseases of the spinal column.

### ADMISSION AND DISCHARGE

Admission to the hospital may be required for further evaluation, testing, and treatment, including further diagnostic testing and consultation, as well as relief of symptoms.

Patients with nonspecific LBP can be discharged home in almost all circumstances; there appears to be limited need or utility in admitting patients for pain control. All patients with LBP who are discharged from the ED should be warned about the risk for CES and be told to return if they experience neurologic or bowel or bladder symptoms.\textsuperscript{14}

Counseling patients with nonspecific LBP that the ED work-up has not found any concerning pathology, that they can expect their pain to get better, and that pain does not necessarily mean danger will help manage their expectations. They should be told to continue their normal activities of daily living as limited by their symptoms. Finally, they should be advised to arrange follow-up with a primary care provider (because possible specific cause, neurologic compromise, or spinal instability).

Patients with specific systemic or visceral sources of their LBP require specialist consultation.

NSAIDs, Nonsteroidal antiinflammatory drugs.

![Documentation](attachment:image)

- Presence or absence of “red flags” suggesting specific, systemic, or visceral sources of the patient’s complaints
- Findings from a systematic neurologic examination of the lower extremities, including sacral nerve function
- Discussion of findings requiring urgent work-up, including consultations (because of a possible specific cause, neurologic compromise, or spinal instability)
- Discussions with patients and their families or friends (specific instructions about follow-up and warning signs suggesting cauda equina syndrome requiring immediate evaluation)
Low back pain is a common problem, with four of every five adults having back pain at some time in their lifetime. The most common causes of low back pain are:

- **Muscle strains and spasm**: Poor posture and improper or excessive lifting or twisting may cause strains or spasms of the muscles that support the back.
- **Degenerative processes**: As people age, the disks between the spine’s bones that provide cushioning and lubrication dry and harden, and the spine stiffens, which leads to pain and discomfort.
- **Sciatica**: Compression or “pinching” of nerves (perhaps from a disk that bulges out from between the backbones) causes pain from the back to travel down the leg.

Treatment of low back pain (what doctors call “conservative therapy”) includes:

1. Over-the-counter pain relievers such as ibuprofen (Advil, Motrin, Nuprin), naproxen sodium (Aleve), and aspirin:
   - Aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) can cause stomach problems and should be taken with food or milk.
   - If you are taking blood thinners, ask your doctor or pharmacist whether it is safe to take NSAIDs or aspirin.
   - Acetaminophen (Tylenol) is less likely than aspirin and other NSAIDs to bother your stomach.
2. Application of ice in the first 24 hours of symptoms, with moist heat on the following days.
3. Gradual return to normal activities, including walking, without the need for special exercises.
   - “Bed rest” does not help and may actually slow the recovery process.

Follow up with your primary care provider to make sure that you are getting better and to help minimize recurrence of your symptoms. If you have back pain plus any of the following signs or symptoms, call your doctor:

- Fever above 100.5°F (38°C)
- Past use of steroids, such as prednisone, for more than 1 week
- Unexplained weight loss
- Pain that gets worse or does not get better when you stop moving and rest or lie flat in bed
- Pain that awakens you from sleep
- An injury to your back from a fall, a car crash, or an assault
- Bladder or bowel problems
- Weakness in your legs, as opposed to pain
- Severe pain despite the use of medications prescribed by your doctor
- A personal history of cancer

REFERENCES

The etiologic factors and mechanisms mediating IPV are both complex and the subject of ongoing dispute by researchers in the field. Known factors associated with increased risk for IPV include poverty, societal and individual views of gender relationships, relationship conflict, alcohol use, and societal views about the use of violence in conflict.6 The sequelae of IPV range from mental health issues and minor injuries to multisystem trauma and death.7

PRESENTING SIGNS AND SYMPTOMS

HISTORY
Victims of IPV often do not disclose their abuse to health providers, and studies have shown that some victims will even deny abuse when directly asked.8 Surveys of IPV victims suggest that women fail to disclose victimization when physicians do not ask about abuse, when patients perceive that the provider lacks time or interest in their disclosure, or when they have concerns about police involvement or loss of confidentiality.9 The probability of IPV disclosure may be increased if clinicians provide a reason for inquiring about abuse, create an atmosphere of concern and support, and provide informational resources about IPV regardless of patient disclosure.8

In addition to direct inquiry by a clinician, recent ED-based studies have found that patient disclosure of abuse is increased when the ED uses an automated system of IPV screening, such as a computer-based screening questionnaire.10

PHYSICAL FINDINGS

Most commonly, IPV victims seek treatment in health care settings for complaints not directly related to their abuse or with obvious physical trauma.11 When IPV victims are seen in the ED with evidence of physical trauma, women who are victims of IPV are more likely to have trauma involving the head, face, neck, thorax, breasts, and abdomen than are women with trauma attributable to other causes.12 In addition, injuries in various stages of healing or defensive injuries may be noted.

Although any pattern or mechanism of injury may be the result of IPV, clinicians should have a low threshold for suspecting IPV when seeing women with blunt trauma to the head, neck, and face (particularly as a result of punching or

KEY POINTS

- The estimated prevalence of intimate partner violence victimization in women accessing emergency departments is as high as 36% in some populations.
- Interpersonal violence occurs across all populations regardless of social, economic, religious, cultural, or sexual orientation factors.
- More than 40% of women murdered by an intimate partner had visited an emergency department within 2 years of the homicide, and more than 90% had at least one visit for an injury.
- The emergency department serves a critical role to screen for, identify, and provide help to victims of intimate partner violence.

EPIDEMIOLOGY

The Centers for Disease Control and Prevention defines intimate partner violence (IPV) as threatened or current physical, sexual, or verbal abuse inflicted by a spouse, former spouse, or current or former boyfriend, girlfriend, or dating partner. Among women alone, IPV is estimated to result in 2 million injuries and 1300 deaths annually. Costs associated with IPV are estimated to be $5.8 million in the United States each year.1 It is estimated that 40% to 60% of homicides of women in the United States occur as a result of IPV.2

Although IPV is commonly thought to affect women and be perpetrated by men, studies suggest that women may be perpetrators of IPV as often as men, but male victims may be less likely to sustain physical injuries and seek medical care.3 Additionally, counter to these perceptions, a recent emergency department (ED)-based study performed in an urban ED found that 31% of men who had been in a relationship during the previous year had experienced some form of IPV victimization.4 In same-sex partners, IPV appears to occur at rates similar to that in heterosexual couples and with similar patterns, types of violence, and inciting factors.5

PATHOPHYSIOLOGY

The etiologic factors and mechanisms mediating IPV are both complex and the subject of ongoing dispute by researchers in the field. Known factors associated with increased risk for IPV include poverty, societal and individual views of gender relationships, relationship conflict, alcohol use, and societal views about the use of violence in conflict.6 The sequelae of IPV range from mental health issues and minor injuries to multisystem trauma and death.7
Acute 

family/partner violence.

Arch of Medicine and Intimate Violence.

decisions regarding safety at home, relationships, and access to

physical assault. KR. Arch Violence. DJ, of Med

Persistent health problems resulting from IPV include chronic headaches; chronic back pain; neurologic symptoms, including fainting and seizures; gastrointestinal complaints, including poor appetite, eating disorders, and irritable bowel syndrome; and cardiac symptoms, including recurrent chest pain and hypertension.13 IPV victimization is also significantly correlated with an increased risk for mental health problems, including depression, suicidality, and posttraumatic stress disorder.13 Long after the abuse has ended, IPV victimization has long-term consequences on health status, quality of life, and use of health care resources11 (Box 93.1).

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The differential diagnosis of injuries attributable to IPV include injuries related to unintentional causes, such as household injuries or motor vehicle collisions, as well as self-inflicted injuries. The cause of the injury may be distinguished by the physical patterns of injury and the history provided by patients, although no approach can entirely rule out the possibility that an injury was caused by IPV. Additionally, IPV victimization should be considered in the differential diagnosis of many patients seen in the ED with complaints unrelated to injury, including depression, abdominal pain, headaches, and chest pain, among others.

If IPV victimization is suspected, the physician should perform a thorough social history, including living situation and perceived safety at home, relationships, and access to

social, familial, and financial support. Even though no diagnostic test can confirm or refute an abuse history, in some cases obtaining radiographic or photographic documentation (or both) of injuries may be useful for subsequent prosecution of the perpetrator (see the Red Flags box).

RED FLAGS

Symptoms and History Suggestive of Interpersonal Violence

Blunt trauma to the head, face, and neck

Frequent headaches

Sexually transmitted diseases

Chronic pelvic pain

Abdominal pain, indigestion, or frequent diarrhea or constipation

Vague history of injury or a history inconsistent with injuries

Injuries in multiple stages of healing

Partner will not leave patient’s side

TREATMENT

Interventions for patients who are known or suspected to be victims of IPV focus on (1) treating any acute injury resulting from the violent incident, (2) ensuring the patient’s physical safety after discharge, and (3) providing referrals and resources to at-risk patients.

In the prehospital and hospital setting, priority should be placed on identifying and stabilizing physical injuries. A complete physical examination and detailed history are a priority because the patient may have prior, incompletely healed injuries that are unrelated to the trauma prompting the present visit.

History taking should focus on the mechanism of injury, as well as inquiries into the patient’s safety at home. A majority of states have laws mandating physicians to report injuries resulting from IPV; clinicians should be aware of laws pertaining to mandatory reporting in the locations where they practice. In addition to facilitating contact with law enforcement agencies, the treating clinician should ensure that the patient and any children will have a safe place to stay after discharge and should facilitate referrals to social services or local support agencies if the patient does not have a safe home setting.

If a clinician suspects that a patient may be at risk for IPV but there is no clear history of recent or current victimization, providing the patient with educational material about the warning signs of at-risk relationships and information about local support organizations and shelters may be appropriate (see the Priority Actions box).
FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

The decision to admit patients victimized by IPV should be dictated by the severity of the injuries or non–trauma-related complaints, as well as the patient's safety at home. If the patient has minor injuries but no safe place to stay, admission may be indicated to allow time for the patient to work with social services staff to ensure safe discharge.

In addition to thorough documentation of the patient’s history of the present illness and findings on physical examination, it is essential that the treating clinician document details about the patient’s home situation, including (1) whether the patient lives with the assailant, (2) whether children are living in the home and plans for ensuring the safety of the children, (3) temporary alternative housing options available to the patient, and (4) whether the patient believes that she will be safe if discharged. In addition, given the high correlation between IPV and depression, the social history should also include inquiries into the patient's substance use, as well as symptoms of depression or any suicidal or homicidal ideation (see the Documentation box).

Altered Mental Status and Coma

Benjamin S. Bassin, Jeremy L. Cooke, and William G. Barsan

PERSPECTIVE

Altered mental status is a spectrum of disease ranging from sleepiness and confusion to frank coma. Approximately 3% of patients arrive at the emergency department (ED) in an altered state.

EPIDEMIOLOGY

Roughly 85% of cases of altered mental status are caused by metabolic or systemic derangements, whereas 15% are caused by structural lesions. Once the ABCs (airway, breathing, and circulation) have been controlled and the patient stabilized, it is the role of the emergency physician (EP) to quickly distinguish structural from metabolic and systemic causes.

PATHOPHYSIOLOGY

Consciousness is collectively made up of arousal and cognition. Arousal is defined as the awareness of self and the surroundings. The neuroanatomic structure primarily responsible for arousal is the ascending reticular activating system, which is located in the dorsal part of the brainstem. It controls the input of somatic and sensory stimuli to the cerebral cortex and functions to initiate arousal from sleep. Cognition is the combination of orientation (accurate perception of what is experienced), judgment (the ability to process input data to generate more meaningful information), and memory (the ability to store and retrieve information). The brain’s cognition centers are located primarily in the cerebral cortex.

Coma can be caused by damage to the brainstem (Fig. 94.1), the cerebral cortex, or both. These structures are vulnerable to toxins, metabolic derangements, and mechanical injury. Localized, unilateral lesions in the cerebral cortex do not usually induce altered mental status or coma, even with other cognitive functions being impaired. However, if both cerebral hemispheres are affected, altered mental status or coma can occur, depending on the size of the insult and its speed of progression. The ascending reticular activating system can also be vulnerable to small, focal lesions in the brainstem.1,2

PRESENTING SIGNS AND SYMPTOMS

The chief complaints of patients and their family members are highly variable along the spectrum of altered mental status. Patients may report increased sleepiness or periods of confusion and disorientation. They may have trouble concentrating or maintaining focus on tasks that were previously performed without difficulty. Family members may describe the patient as being less interactive or more difficult to arouse from sleep.

Regardless of the circumstance, the EP will frequently need to use alternative sources of information to answer key historical questions that may alter the breadth and speed of the diagnostic work-up undertaken. Common sources of information include family members, neighbors, prehospital personnel, law enforcement, and nursing home staff.3 They may know of preceding symptoms such as headache, nausea, vomiting, or fever. It is important to determine the rate of symptom onset and whether the patient had any history of trauma, exposure to drugs or toxins, or new medications or change in dosage. Family members usually have some knowledge regarding the patient’s past medical history. Additionally, previous medical records should be reviewed whenever possible to confirm or augment the information provided. If the patient’s historical baseline mental status cannot be established, the current findings must be assumed to be an acute change.3

KEY POINTS

- Because the differential diagnosis of coma is broad, a systematic approach to patient evaluation and diagnostic testing is required.
- Patients with altered mental status may have subtle neurologic dysfunction, so careful neurologic examination is necessary.
- Quickly reversible causes should be sought before the initiation of a more lengthy diagnostic work-up. Naloxone, dextrose, and thiamine administration should be considered initially in patients with undifferentiated coma.
- Structural brain lesions that may require operative intervention dictate immediate consultation with a neurosurgical service.
The age of the patient can be a key historical tool that may focus the physician on the most probable cause of the patient’s symptoms (Box 94.1).

In infants, infectious causes of altered mental status are most common; however, nonaccidental trauma and metabolic derangements from inborn errors of metabolism are also possible causes. Toxic ingestions are commonly seen in young children. Adolescents and young adults are often seen in the ED after recreational drug use. The elderly are particularly susceptible to infectious causes and to disorders related to changes in medications or drug doses, use of over-the-counter medications, and alterations in their living environment. Psychiatric illness should be considered in the adolescent through elderly population and must be distinguished from medical illness as a cause of the patient’s symptoms.

As with all patients, specific attention should first be paid to assessment of the ABCs and specific vital signs. Alterations in respiratory patterns such as hyperventilation, Kussmaul or Cheyne-Stokes breathing, agonal breathing, or apnea should be noted and may suggest toxic or metabolic derangements or primary central nervous system abnormalities. Marked hypotension or hypertension should be addressed immediately even if the underlying cause is unknown. Bradycardia may be the result of increased intracranial pressure as seen in the Cushing response and suggests a state of hypoperfusion. Tachycardia may also result in hypoperfusion and can be the result of toxic, metabolic, or primary cardiac causes. Assessment of temperature is crucial because both hypothermia and hyperthermia can cause altered mental status from infectious, structural (Box 94.2), environmental exposure, or toxic or metabolic causes (Box 94.3).

Any signs of trauma should be sought immediately. Scalp lacerations or hematomas, depressed skull fractures, hemo tympanum, raccoon eyes, Battle sign, cerebrospinal fluid otorhinorrhea, cervical spine step-offs, and crepitus all suggest a traumatic cause. Other signs of trauma include lesions on the chest, abdomen, or pelvis; long-bone deformities; and gross blood in the rectum or vagina or at the urethral meatus.

In the absence of trauma, breath odors may be helpful, including the smell of alcohol, ketones (diabetic or alcoholic ketoacidosis), and bitter almonds (cyanide toxicity). Abdominal findings include ascites, hepatosplenomegaly, ecchymosis, and striae. Lesions on the skin such as rashes, signs of drug use (needle tracks, medication patches), and embolic phenomena can be telling.

†Prominent in the pediatric population.

NEUROLOGIC EVALUATION

A systematic neurologic examination is a key tool in determining whether the cause is structural, systemic, or metabolic. The basic examination includes evaluation of the patient’s level of alertness, cranial nerves, strength, sensation, reflexes, gait, and cerebellar function.

The Glasgow Coma Scale (GCS) can be used to assess the patient’s level of consciousness. The GCS does not differentiate between causes of altered mental status or coma or assess cognition. However, it is useful in monitoring changes in mental status when serial examinations are performed and serves as an objective reference when communicating with consultants (Table 94.1).

A focal neurologic deficit usually suggests a structural cause. Pupillary findings such as unilateral dilation or a “blown pupil” and loss of reactivity indicate uncal herniation, which is a neurosurgical emergency. Funduscopic examination can demonstrate hemorrhage in the setting of trauma or papilledema, which suggests increased intracranial pressure.

Testing of eye movements is a hallmark in the neurologic examination of patients with altered mental status or coma. Eye movements are coordinated by ocular centers in the cerebral cortex and the medial longitudinal fasciculus located in the brainstem. The extraocular muscles are innervated primarily by cranial nerves III, IV, and VI. Disconjugate gaze in the horizontal plane is common and can be associated with sedated or drowsy states or alcohol intoxication. Disconjugate gaze in the vertical plane is more ominous and points to pontine or cerebellar lesions. A persistently adducted eye is caused by cranial nerve VI paresis, whereas a persistently abducted eye is caused by cranial nerve III paresis. These are nonlocalizing lesions; however, elevated intracranial pressure or mass effects from trauma, for example, can compromise cranial nerve functions via extrinsic compression. In the absence of contraindications, oculocephalic (doll’s eyes) or oculovestibular reflex testing can be very helpful. If intact, these reflexes demonstrate functional integrity of a significant
The majority of the brainstem, thus making it exceedingly unlikely as the anatomic location for the cause of the patient’s altered mental status.1,2,5,7

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The differential diagnosis of altered mental status and coma is extensive and can be daunting for the busy EP (see Boxes 94.1 to 94.3). Fortunately, there are many distinguishing features in the physical examination that, when combined with information gleaned from the patient’s history of the present illness, past medical history, and response to therapy (i.e., dextrose, naloxone), point to a particular cause and are frequently of greater diagnostic value than imaging, electrocardiograms (ECGs), and laboratory tests.1 However, a systematic approach is best and reduces the likelihood of missing an important clue.1,2,8

DIAGNOSTIC TESTING

Diagnostic testing in patients with altered mental status or coma is based on information gathered from the history and physical examination, which in most cases will point toward a structural versus systemic or metabolic cause. Extensive metabolic work-ups should not precede neuroimaging studies in patients with altered mental status or coma that may be due to structural causes. Similarly, treatment of suspected narcotic overdose or hypoglycemia should not be delayed in favor of imaging studies. However, in undifferentiated patients, diagnostic tests should be performed in parallel whenever possible to avoid unnecessary delays in initiating treatment. A general approach to the diagnostic work-up of patients with altered mental status or coma is shown in Figure 94.2.

LABORATORY EVALUATION

Basic laboratory studies are useful in determining the most common metabolic causes of altered mental status. Capillary blood glucose measurement, both prehospital and on arrival at the ED, can often avoid further extensive work-ups, especially in patients with diabetes or alcohol intoxication. Serum electrolytes and renal function studies may demonstrate an anion gap acidosis or significant sodium or potassium imbalance or uremia. Serum calcium may be a marker for metastatic disease, and severe hypercalcemia can be associated with altered mental status.

A complete blood cell count may demonstrate profound anemia from witnessed or occult blood loss. A low white blood cell count raises concern for an immunocompromised state, but an elevated white blood cell count is less helpful in making the diagnosis as a nonspecific marker for infection, inflammation, or stress. Low platelet levels may indicate sepsis, disseminated intravascular coagulation, or intracranial bleeding. Serum coagulation studies may be performed to look for bleeding dyscrasias or supratherapeutic levels of anticoagulants (warfarin) or, when combined with other liver function studies, may provide evidence of liver dysfunction. Both platelet counts and coagulation studies should be performed before obtaining central venous access and performing lumbar puncture or other invasive procedures if time or the patient’s condition allows. Checking the serum ammonia level is controversial; it has not been shown to be a reliable marker for the cause of altered mental status because it can be normal in patients with hepatic encephalopathy but can also be elevated in those with acute hepatic failure from other causes, as well as valproic acid toxicity and inborn errors of metabolism.7

Thyroid function studies are useful in patients with suspected myxedema coma secondary to hypothyroidism. Arterial blood gas (ABG) analysis can demonstrate hypercapnia or hypoxia and aid in the classification of acid-base disturbances. Cooximetry can be added to ABG analysis to determine carbon monoxide levels or methemoglobinemia. In the absence of contraindications, cerebrospinal fluid analysis is mandatory when considering a central nervous system infectious cause or to rule out subarachnoid hemorrhage after a negative, non–contrast-enhanced computed tomography (CT) scan of the brain.

Urinalysis is a useful tool that provides information about volume status (specific gravity), spilling of glucose as in hyperosmolar coma, and evidence of infection, which is a common cause of altered mental status in the elderly. Urine drug screening for illicit drug use as a cause of altered mental status is often less helpful unless other causes are not forthcoming, but it may help confirm a suspected diagnosis. Microscopic analysis of urine can reveal calcium oxalate crystals in the setting of ethylene glycol ingestion.

IMAGING

The mainstay of diagnostic imaging in the setting of altered mental status is non–contrast-enhanced CT of the brain. It is fast and readily available in most ED settings and can reveal the vast majority of intracranial hemorrhages large enough to induce coma. Hydrocephalus is also readily detected on non–contrast-enhanced CT. If subarachnoid hemorrhage is suspected, negative CT findings should be followed by lumbar puncture. When tumor or infection is suspected, contrast-enhanced CT may be indicated.

A limitation of brain CT scanning is the potential poor view of the posterior fossa as a result of linear artifacts created by the thick skull base. Magnetic resonance imaging (MRI) of the brain is more helpful in identifying structural lesions in this area; however, its cost and limited availability, as well as the inability to monitor unstable patients, make this imaging modality less feasible in some ED settings.4 CT angiography or venography may be available for the diagnosis or treatment (or both) of vertebral or basilar artery stenosis or occlusion, intracerebral aneurysms, cerebral venous sinus thrombosis, or arteriovenous malformations. If brain abscess or metastatic lesions are a concern, contrast-enhanced head CT can be useful in making the diagnosis.

Other diagnostic tools include plain radiography, which can reveal serious pneumonia, acute respiratory distress syndrome, ingested illicit substances seen in “body packers,” or specific types of ingestions such as mercury, iron, and lead. This can be particularly helpful in the pediatric population when the history is not reliable. ECGs are useful for diagnosing certain ingestions (e.g., tricyclic antidepressants), electrolyte abnormalities (e.g., potassium, calcium), and hypothermia. Though not commonly used in the ED, electroencephalographic monitoring is mandatory for comatose patients with suspected status epilepticus.
**TREATMENT**

Initial stabilization and quick control of the ABCs are paramount in patients with altered mental status. Patients should be placed immediately on telemetry with concomitant administration of oxygen and initiation of intravenous access. Definitive airway control with endotracheal intubation is critical in patients without a gag reflex or with a GCS score lower than 8. Lidocaine premedication should be used for rapid-sequence intubation in patients with suspected elevated...
intracranial pressure. In the setting of trauma, maintaining spinal precautions with a backboard in addition to initiation of intravenous fluid therapy is mandatory.

Once initial stabilization has been addressed, reversible causes must be sought. A bedside ECG and capillary blood glucose test should be obtained immediately. Blood and urine should be sent to the laboratory for studies early after the patient’s arrival, and the patient should be scheduled for emergency head CT. Empiric administration of a “coma cocktail” consisting of dextrose, thiamine, and naloxone is controversial but may bring immediate results and significantly narrow the differential diagnosis.

Physical examination with specific attention to brainstem function dictates further work-up and therapy. Patients whose brainstem function is compromised with evidence of brain herniation require immediate evaluation by neurosurgery. Empiric therapy with mannitol may be indicated in this setting. Evidence of brain herniation secondary to a traumatic cause may necessitate the use of burr holes on the side of the dilated pupil as a last resort. Ventriculostomy and monitoring of intracranial pressure are often performed by a neurosurgeon in the ED.

Patients with compromised brainstem function but no evidence of herniation should have immediate consideration for basilar artery or bilateral vertebral artery occlusion and undergo CT or magnetic resonance angiography while receiving supportive care with a concomitant toxic and metabolic work-up. Patients are considered to have unsalvageable brain tissue if they have no brainstem reflexes, have not received neuroactive medications, and are normothermic.

In patients whose brainstem function is intact, supportive care is provided while the work-up proceeds. Lesions discovered on brain CT require immediate evaluation by neurosurgery. In general, patients with operable lesions are transferred immediately to the operating room; patients with inoperable lesions continue to receive supportive care. In cases in which an infectious cause is suspected, empiric antibiotic coverage should not be delayed for lumbar puncture or other diagnostic modalities.

In the setting of suspected toxic ingestion, activated charcoal with or without sorbitol is indicated. Gastric lavage has been used in patients with recent (less than 60 minutes since ingestion), potentially lethal toxic ingestion (e.g., tricyclic antidepressants, beta-blockers); however, this intervention is somewhat controversial and associated with potential complications, including aspiration and esophageal damage. Specific antidotes, if applicable based on the history and physical examination, should be initiated early. Finally, early hemodiagnosis should be considered in patients who have ingested substances amenable to this therapeutic modality.10

**ADMISSION AND DISCHARGE**

The majority of patients who have significant alterations in mental status require admission for further work-up and treatment. The exception is patients with an easily reversible cause, such as opiate overdose or hypoglycemia, who may be discharged after a period of observation during which there is a return to baseline mental status. In addition, patients with alcohol intoxication and no other cause of altered mental status may be discharged once they are deemed clinically sober. Placement in an intensive care unit setting is usually appropriate for patients whose mental status is persistently altered.

Immediate consultation with the neurosurgical service is paramount for patients with potentially operable lesions. After definitive airway control and stabilization of vital signs, rapid transfer to a center with neurosurgical diagnostic and therapeutic capabilities should be sought if the necessary resources are not available locally.

diabetes and hypertension are common comorbid conditions. Cranial nerves I, VI, and VII are the most frequently affected after minor head trauma.1 Trigeminal neuralgia is a common cause of facial pain that affects approximately 4.5 per 100,000 individuals; women are affected twice as often as men, and it is more common in those older than 60 years.2 Trigeminal neuralgia can be severely debilitating and has been termed the “suicide disease.”3 Bell palsy is the most common cause of acute facial paralysis worldwide. The peak age at incidence has been reported to be between 15 and 45 years,4 but other investigators have noted an increased incidence in individuals older than 70.5,6 Pregnant women and patients with diabetes have an associated increased incidence of the disease. A familial association of Bell palsy is noted in 4% of cases,4 and it can cause both significant psychologic and physical morbidity.

PATHOPHYSIOLOGY

CRANIAL NERVE I (OLFACTORY NERVE)

Anatomy
Cranial nerve I is a special sensory nerve that provides the sense of smell. Inhaled scents are detected by the olfactory epithelium lining the nasal cavity and transmitted to the olfactory bulb, which lies adjacent to the cribriform plate of the ethmoid bone. Olfactory sensations are relayed from the olfactory bulb to the brain via the olfactory tract.

Presenting Signs and Symptoms
The patient should be questioned about a history of head trauma. An anteroposterior skull fracture parallel to the sagittal suture or an anteroposterior shearing injury can tear the olfactory fibers traversing the cribriform plate and lead to disruption of the synapses from the olfactory epithelium to the olfactory bulb.

A frontal lobe mass such as a tumor, meningioma, or abscess can compress the olfactory bulb as well, but the signs and symptoms associated with such masses tend to be more subacute.

Treatment
Treatment depends on the presence of concomitant injury. Basilar skull fracture and cerebrospinal fluid rhinorrhea associated with trauma require immediate neurosurgical consultation. A subacute mass or abscess should be managed in
consultation with neurosurgery, depending on the acuity of the findings. Patients with anosmia secondary to trauma and normal findings on head computed tomography (CT) can referred to neurology or neurosurgery for outpatient follow-up.

**CRANIAL NERVE II (OPTIC NERVE)**

**Anatomy**

Visual stimuli are transmitted from the retina to the optic nerve through the optic chiasm to the lateral geniculate nucleus in the thalamus, where they synapse. From there, impulses are transmitted along the optic radiations (geniculocalcarine tracts, including the Meyer loop) to the primary visual cortex in the occipital lobes.

**Presenting Signs and Symptoms**

Unilateral loss of vision is most common with injuries to the optic nerve. Patients with bilateral visual loss may not be aware of any such injury until an examination is performed. Acute visual loss is often of vascular origin, including central retinal arterial or venous occlusion and cerebrovascular disease. Neurologic causes, such as multiple sclerosis, may be suggested by progression of the visual loss over a period of days or weeks, pain, and a history of additional neurologic symptoms. Inflammatory processes such as optic neuritis may be the initial symptom of multiple sclerosis.

Neuropathy from temporal arteritis usually occurs in elderly patients and is associated with progressive loss of vision (unilaterally or bilaterally), constitutional symptoms, jaw claudication, and headache.

Idiopathic intracranial hypertension should be considered in patients with a history of headache, visual scotomata, and visual changes. The typical patient is a young, heavy-set woman who is taking oral contraceptives. The headache and visual changes are typically worsened by coughing, bending over, or performing techniques such as the Valsalva maneuver.

Orbital compressive tumors or aneurysms cause mass effects that compromise optic nerve function.

**Differential Diagnosis**

The differential patterns of visual loss are described in Box 95.1.

**Treatment**

Treatment depends on the cause. Emergency ophthalmologic consultation is essential for vascular causes. Treatment of central retinal artery occlusion should focus on lowering intraocular pressure. Inpatient evaluation for neurologic causes is warranted depending on the clinical findings. Temporal arteritis requires high-dose steroid therapy. Idiopathic intracranial hypertension requires urgent diagnostic and therapeutic lumbar puncture.

**CRANIAL NERVE III (OCULOMOTOR NERVE)**

**Anatomy**

The oculomotor nerve is a pure motor nerve that works in conjunction with cranial nerves IV and VI to coordinate extraocular movements. The oculomotor nerve controls the superior rectus (globe elevator), medial rectus (globe adductor), inferior rectus (globe depressor), and inferior oblique (globe elevator) muscles. It also controls the levator palpebrae superiors muscle (upper eyelid elevator) and the intrinsic visceral motor function of the sphincter pupillae muscles and the ciliary muscles, which perform pupillary constriction and accommodation, respectively.

**Presenting Signs and Symptoms**

The patient typically complains of double vision or difficulty seeing out of the affected eye. There may be mild photophobia in bright light. The patient may also complain of an inability to raise the eyelid (ptosis).

Cranial nerve III palsy is more common in patients older than 60 years and in those with diabetes or hypertension (Fig. 95.1).

Patients with herniation syndromes will have a history of trauma (Fig. 95.2), tumor, or other neurologic findings.

Pain associated with unilateral mydriasis should alert the emergency physician (EP) to look for an aneurysm involving the terminal internal carotid artery. Computed tomographic

---

**BOX 95.1 Differential Patterns of Visual Loss**

A central retinal etiology of the fovea or optic disk compromises visual acuity or causes central loss of vision in the affected eye only.

Unilateral blindness is usually associated with an optic nerve lesion, and only the affected eye has complete visual field loss.

Unilateral nasal visual field loss can be caused by an internal carotid artery aneurysm compressing the lateral optic chiasm.

Bitemporal hemianopia can be caused by a midchiasmatic lesion.

Homonymous hemianopia from an optic tract lesion causes full contralateral visual field loss in both eyes.

Homonymous quadrantanopia secondary to a Meyer loop lesion causes contralateral one-quarter visual field loss in both eyes.

---

**Fig. 95.1** This 60-year-old man had diabetes mellitus, hypertension, coronary artery disease, chronic renal failure, and multiple myeloma. He sought medical care because of double vision (he described the images as “a little side by side but mostly up and down”), diplopia, ptosis, and papillary sparing. Findings on laboratory tests, magnetic resonance imaging, and magnetic resonance angiography were negative. The patient was evaluated by a neurologist and an ophthalmologist, and diabetic cranial nerve palsy was ultimately diagnosed. He was given an eye patch and scheduled for ophthalmologic follow-up.
Patients with an abscess or cavernous sinus thrombosis may have headaches, altered mental status, and seizures. This diagnosis should be considered in patients with signs and symptoms in the contralateral eye, previous sinus or midface infection, fever, chemosis, eyelid or periorbital edema, and exophthalmos. Extension of internal carotid artery dissection intracranially into the cavernous sinus can result in third, fourth, and sixth cranial nerve palsies.9

**Treatment**

Treatment is dependent on the cause. CT should be performed to exclude a herniating mass. Admission for magnetic resonance imaging (MRI) and neurology or neurosurgical consultation is indicated for acute-onset deficits.

**CRANIAL NERVE IV (TROCHLEAR NERVE)**

**Anatomy**

The trochlear nerve innervates the superior oblique muscle of the eye and causes inward rotation and downward and lateral movement of the globe. It is the smallest cranial nerve but has the longest intracranial course.

**Fig. 95.3** A, Normal eye rotation. When the head tilts to the left, both eyes rotate in the opposite direction (right eye extorts, left eye intorts). B, Cranial nerve IV palsy (right eye). The right eye is extorted and slightly elevated, which is causing double vision. To compensate, the patient tilts her head to the left.

**Presenting Signs and Symptoms**

Patients with a fourth cranial nerve palsy have double vision exacerbated by looking downward. The classic complaint is difficulty going down stairs. Most commonly, a history of trauma is reported. On physical examination the patient may unconsciously tilt the head away from the affected side (Fig. 95.3). Etiologic mechanisms are similar to those for the third cranial nerve and include inflammatory processes, trauma, and vascular causes.10

**Treatment**

Treatment of isolated fourth nerve palsy is generally conservative, and the patient should be referred to neurology or neurosurgery as appropriate.10 CT, MRI, and neurology consultation are warranted if multiple cranial nerves are involved.

**CRANIAL NERVE V (TRIGEMINAL NERVE)**

**Anatomy**

The trigeminal nerve is a mixed motor and sensory nerve. It provides motor innervation to the muscles of mastication, as well as sensation from the face, scalp, conjunctiva, globe, mucous membranes of the sinuses, tongue, teeth, and part of the external tympanic membrane.

The trigeminal sensory ganglion is located in the middle cranial fossa and branches into three divisions: the ophthalmic nerve (V1), the maxillary nerve (V2), and the mandibular nerve (V3).

**Presenting Signs and Symptoms**

Patients with trigeminal nerve dysfunction have either sensory or motor deficits. Sensory dysfunctions include paroxysmal pain, paresthesias (abnormal sensations such as burning, pricking, tickling, or tingling), dysesthesias (disagreeable, unpleasant, or painful sensations produced by ordinary stimuli), and anesthesia (loss of sensation). The motor dysfunction is usually described as difficulty chewing and difficulty swallowing.

Peripheral lesions cause loss of sensation or pain in only one division. Positive findings in two or more divisions (e.g., loss of light touch in one division and loss of sensitivity to pain, temperature, or pinprick in another division) should raise suspicion for a central cause.
The presence of associated cranial nerve deficits (III, IV, V, or any combination of these nerves) suggests cavernous sinus involvement. In the setting of trauma, if a bruit over the orbit can be detected, a carotid–cavernous sinus fistula may be present. Associated involvement of cranial nerve VII or VIII or gait ataxia should raise suspicion for a cerebellopontine angle or lateral pontine tumor (Table 95.1).

Associated Horner syndrome may indicate a cervical or lateral brainstem lesion.

The main categories of trigeminal nerve dysfunction are trigeminal neuralgia and trigeminal neuropathy. A sudden onset of symptoms should raise suspicion for a vascular, traumatic, or demyelinating cause, whereas a more indolent course suggests tumor or inflammation (Table 95.2).

**TRIGEMINAL NEUROPATHY** Causes include compression by an extrinsic mass, trauma, and vascular, inflammatory, or demyelinating disorders.

Symptoms include neuralgia or paresthesia (or both) involving half of the face. Unlike trigeminal neuralgia, the pain with trigeminal neuropathy is more constant. Loss of the corneal reflex is evident. The patient’s mouth may become more oval.

AIDS, Acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.
and oblique in appearance, and because of loss of masseter muscle strength, the chin may be deviated toward the affected side.

Until proved otherwise, neuropathies of cranial nerve V, the chin (numb chin; V3), and the suborbital region (numb cheek) should be presumed to be due to malignancies.\textsuperscript{11}

TIC DOULOUREUX The term tic douloureux was coined by Nicolaus André, a French surgeon, in 1756. Its mechanism is probably compression of the trigeminal nerve root within millimeters of entry into the pons.\textsuperscript{12} The maxillary and mandibular divisions are most commonly affected, either alone or in combination. In one longitudinal case series, no cases of trigeminal neuralgia affecting both the ophthalmic and mandibular divisions were reported.\textsuperscript{2} Causes of tic douloureux are listed in Box 95.2.

The International Association for the Study of Pain defines tic douloureux as “a sudden usually unilateral, severe, brief, stabbing, recurrent pain in the distribution of one or more branches of the fifth cranial nerve.” The pain is classically precipitated by normal activities such as eating, talking, washing the face, or cleaning the teeth.

Diagnostic Testing
The presence or absence of a corneal reflex should be checked. An intact reflex indicates normal function of the afferent V1 division, as well as normal cranial nerve VII motor efferent function. Absence of a corneal reflex can be caused by tumors in the posterior fossa or cerebellopontine angle, multiple sclerosis, brainstem strokes (Wallenberg or lateral medullary syndrome), and Parkinson disease.

Motor function is evaluated by having the patient open and close the mouth and laterally deviate the jaw against resistance. Loss of muscle bulk or the presence of fasciculations in the temporalis or masseter musculature indicates a lower motor neuron lesion.

The jaw jerk reflex test determines the integrity of the V3 division. The examiner places a thumb on the patient’s chin, after which the patient is instructed to relax the jaw completely with the mouth closed, and the examiner then taps the chin to elicit the jaw jerk reflex. The reflex will be diminished in patients with a lower motor neuron lesion and accentuated in patients with a supranuclear lesion.

Treatment
A trial of carbamazepine can be therapeutic as well as diagnostic because failure to improve with carbamazepine suggests some other cause. Treatment options are listed in Box 95.3.\textsuperscript{3} Surgical approaches are considered when medication cannot control the pain or pain medication is not tolerated.\textsuperscript{13}

CRANIAL NERVE VI (ABDUCENS NERVE)

Anatomy
The abducens nerve is a pure motor nerve that supplies the ipsilateral lateral rectus muscle of the eye and controls globe abduction.

PRESENTING SIGNS AND SYMPTOMS
Patients with an abducens nerve palsy usually complain of double vision. The head may be turned away from the affected side to maintain binocularity. Diabetes and hypertension are common risk factors. Another common sign is “crossed eyes” (esotropia or strabismus) (Fig. 95.4).\textsuperscript{14}

Differential Diagnosis
Children are more likely to have a tumor as the principal cause, and older individuals are more likely to have an ischemic cause such as temporal arteritis.

An abducens nerve palsy occurring in isolation is rare. Usually, the seventh and eighth cranial nerves are also involved, which signals a central cause. Causes of abducens nerve palsy are listed in Box 95.4.

**Treatment**

Truly isolated sixth nerve palsies are often caused by microvascular ischemia secondary to hypertension or diabetes. A thorough work-up must be performed to rule out a central, inflammatory, infectious, or neoplastic cause. Close follow-up by a neurologist over a 6-month period is indicated; most cases resolve within 3 to 6 months.

**CRANIAL NERVE VII (FACIAL NERVE)—BELL PALSY**

**Mechanisms**

The pathophysiology of Bell palsy has not been clearly established. Several theories have been proposed, including infectious or ischemic inflammation leading to nerve compression within the narrow canal as the nerve exits the stylomastoid foramen. Because the nerve is encased in a tight dural sheath within the temporal bone, this edema then causes additional compression of the vascular supply to the nerve.15

The cause of Bell palsy is most commonly idiopathic (66%).4 Numerous observed associations have been described in the literature. The palsy is often preceded by a viral syndrome, and a correlation has been noted with herpes simplex virus (HSV). Its association with shingles and the characteristic blistering (from varicella-zoster virus [VZV]) is given the designation Ramsay Hunt syndrome. Reactivation of VZV has also been theorized as a cause. In addition, Bell palsy may be seen in patients with Lyme disease in places where the disease is endemic.

Diabetes, hypertension, human immunodeficiency virus infection, sarcoidosis, Sjögren syndrome, parotid nerve tumors, eclampsia, amyloidosis, and the intranasal influenza vaccine have been associated with the development of Bell palsy.5,16 Other common triggers include stress, trauma, fever, tooth extraction, and a chilling episode from exposure to drafts and cold.

Complete facial weakness, severe non–ear-related pain (e.g., retroauricular, cheek), late onset of recovery or no recovery by 3 weeks, diabetes, pregnancy, age older than 60 years, hypertension, and Ramsay Hunt syndrome are risk factors for incomplete recovery.17,18

Electroneurographic studies demonstrate a steady decline in electrical activity on days 4 to 10. When excitability is retained, 90% of patients recover fully, but when excitability diminishes to absence, only 20% of patients recover completely.5

**Anatomy**

Cranial nerve VII is a mixed motor and sensory cranial nerve, which accounts for the varied symptoms. It travels adjacent to cranial nerves V, VI, and VIII as it traverses the cerebellopontine angle, the internal auditory meatus, and the temporal bone.

Motor function involves the muscles of facial expression, the posterior digastric muscle, the stylohyoid muscle, and the stapedius muscle of the inner ear.
Parasympathetic innervation includes the lacrimal glands, the mucous membranes of the nose, the hard and soft palate, and the submandibular and sublingual glands.

The geniculate ganglion contains the nerve cell bodies of the sensory taste fibers of the anterior two thirds of the tongue.19

Presenting Signs and Symptoms
To the patient, the most alarming symptom of Bell palsy is the abrupt onset of unilateral facial paralysis. Approximately 50% of patients believe that they have suffered a stroke, 25% think that they have an intracranial tumor, and the remaining 25% have no clear conception of what is wrong but are extremely anxious.4

The EP may note drooping of the eyebrow or the corner of the mouth (or both) and loss of wrinkles on the forehead or the nasolabial folds (or both). Inability to raise the eyebrow and furrow the forehead is a cardinal sign of Bell palsy (Fig. 95.5). Preservation of forehead motor neuron innervation should raise suspicion for a central cause.17 Because the forehead receives bilateral upper motor neuron innervation, a central stroke will spare the forehead and allow the patient to raise the eyebrow. If the patient can do this, it is not Bell palsy.

Loss of nasolabial fold and nasal flaring is common. Loss of buccinator strength causes an inability to blow out the cheeks. An inability to close the eye on the affected side is a hallmark of Bell palsy. Speech is affected and may sound slurred or garbled, similar to dysarthria from a stroke. An asymmetric smile is often noted on examination (Fig. 95.6).

The signs and symptoms vary depending on the site of the affected nerve. They are listed in Box 95.5.

![Fig. 95.5 “Raise your eyebrows.” A patient with a peripheral seventh nerve palsy (i.e., Bell palsy) will have loss of forehead wrinkles at rest and an inability to wrinkle the forehead and raise the eyebrow on the affected side (right side in this patient).](image1)

![Fig. 95.6 “Show me your teeth”; “wrinkle your nose.” The risorius and orbicularis oris muscles are denervated. Notice the inability to corrugate the nose on the affected right side because of loss of function of the nasal and buccal musculature.](image2)

**Box 95.5 Signs and Symptoms of Bell Palsy**

- Ipsilateral tongue numbness
- Loss of taste or a dull taste
- Overt paralysis preceded by a sensation of subjective numbness or weakness on the affected side
- Ear pain in the external auditory canal
- Retroauricular pain
- Occipital headache
- Hyperacusis
- Fullness or snapping sound in the affected ear
- Tinnitus
- Drooling
- Inability to keep liquids in the mouth or chew
- Noticeable dryness of the oral and nasal mucous membranes on the affected side
- Anxiety

Diagnostic Testing and Differential Diagnosis
The “blow out your cheeks” test (Fig. 95.7) demonstrates loss of buccinator function. A sensitive variation of this test is to ask patients to hold water in their mouth and contract the buccal muscles. The water will either dribble out of the corner of the mouth or shoot across the room.

On testing of hearing, hyperacusis may be observed on the affected side because of denervation of the stapedius. The patient should have no hearing loss.
To evaluate taste sensation, a few granules of sugar are placed on the tip of the patient’s tongue on the affected side. Decreased taste sensation may be noted.

Other cranial nerves should be normal. The abducens nucleus lies at the level of the genu of cranial nerve VII; infarction in the area can cause concomitant palsy of cranial nerve VI, which signals an upper motor neuron lesion rather than Bell palsy. No evidence of expressive or receptive aphasia should be present.

The presence of vesicles on the tympanic membrane or in the oropharynx (Fig. 95.8) or the presence of grouped vesicular lesions on the face or around the ear (Fig. 95.9) suggests a diagnosis of Ramsay Hunt syndrome.

Residual synkinesis can result from abnormal regeneration of nerve fibers. This can be manifested as abnormal motor function (e.g., blinking causes involuntary contracture of the risorius); as abnormal parasympathetic function, which is classically accompanied by “crocodile tears”—lacrimation after a salivary stimulus; or as hemifacial spasm, which can be bothersome, especially when the patient is tired.

**Fig. 95.7** “Blow out your cheeks.” Loss of buccinator function prevents pursing of the lips and allows air (and food and liquids) to escape.

**Fig. 95.8** Buccal herpetic lesions in an individual with Ramsay Hunt syndrome.

**Fig. 95.9** Characteristic auricular rash of Ramsay Hunt syndrome.

**Treatment**

The algorithm shown in Figure 95.10 outlines the treatment of patients with Bell palsy.

Patients can be discharged home with oral medication, instructions for eye care, and expedited follow-up with a neurologist. Additional investigation for Lyme disease may be indicated for patients at risk.

The evidence available indicates that steroids are safe and effective in shortening the course of the neurologic deficit and improving facial function. Patients receiving steroid therapy are up to 1.2 times more likely to attain good functional outcomes than untreated patients are. Corticosteroids reduce the risk for unsatisfactory recovery by 9%, with the number needed to benefit (NNTB) being 11. Corticosteroids were also associated with a 14% absolute reduction in risk for synkinesis and autonomic dysfunction, with an NNTB of 7.

No studies have demonstrated significantly worse facial functional outcomes in patients treated with steroids.

The most commonly reported treatment regimen is oral prednisone, 1 mg/kg up to 70 mg/day for a 10-day course. Dosing can be once daily or split into twice daily. The starting dose is continued for 6 days and tapered over the next 4 days. Alternatively, prednisone, 1 mg/kg/day, may be given for 7 days without a taper.

Recent studies and metaanalyses have questioned the benefit of using antivirals for the treatment of Bell palsy. Antiviral agents used alone did not provide any benefit over placebo, and their use as the sole therapeutic agent is not recommended. When combined with corticosteroid therapy, antiviral therapy may have incremental benefit, but this remains to be shown conclusively. Therefore, until definitive studies are performed, clinical judgment will probably guide the use of antiviral therapy in cases in which a viral cause is strongly suspected (i.e., patients in whom HSV or VZV is
CRANIAL NERVE VIII (VESTIBULOCOCHLEAR NERVE)

Anatomy

The vestibulocochlear nerve is a special sensory nerve that transmits auditory signals from the cochlea (hearing) and signals from the semicircular canals (balance). The vestibular apparatus also sits in the petrous temporal bone and is composed of a body consisting of the saccule and utricle and three semicircular canals aligned in three different planes. Hair cells within the endolymph of the canals detect angular movement and transmit the impulses to the vestibular nuclear complex in the floor of the fourth ventricle. The hair cells collectively combine to form the vestibular ganglion.

Presenting Signs and Symptoms

Patients with vestibulocochlear nerve dysfunction usually exhibit various degrees of hearing loss, tinnitus, vertigo, falling, and imbalance. The mechanism is asymmetric integration of vestibular input to the central nervous system or asymmetric disruption of sensory input from the vestibular organs. If the vertigo is severe, nausea and vomiting also occur. Symptoms may be constant or episodic. Vestibular neuronitis causes vertigo that lasts for weeks, and central vertigo may persist for years.

Patients should be asked about triggers, particularly positional triggers because this may indicate benign paroxysmal positional vertigo. Recent viral and upper respiratory tract infections may be significant because they predispose to vestibular neuronitis. The history should also include the use of medications such as anticonvulsants, antihypertensives, sedatives, and ototoxic drugs.

The examination should be focused on determining reproducibility of the symptoms, gait, balance, and ataxia; on evaluation of possible acute stroke symptoms; and on the character of the nystagmus and severity of the ataxia. The presence or absence of associated cerebellar signs such as lateralizing dysmetria, motor weakness, sensory loss, and abnormal reflexes should be noted, as well as the Babinski reflex and cranial nerve abnormalities such as ophthalmoplegia, dysarthria, and Horner syndrome. Abnormalities in cerebellar function should prompt consideration of a central cause. Patients should also be examined for vertical and rotary nystagmus, which are not typically present in patients with peripheral vertigo; their presence warrants imaging and neurologic evaluation.

Diagnostic Testing and Differential Diagnosis

The Dix-Hallpike maneuver is commonly used to elicit positional nystagmus (see Fig. 96.1), which is associated with benign paroxysmal positional vertigo and usually lasts 5 to 60 seconds. Prolonged nystagmus is unlikely to be a result of this disorder. Gait and balance can be assessed with tandem walking and the Romberg test. Ataxia and lateralizing dysmetria can be assessed with finger-to-nose and heel-knee-shin testing. Hearing can be evaluated with the finger rub or finger snap, the Weber test, and the Rinne test. The ear and external auditory canal should be examined for evidence of cerumen.

Fig. 95.10 Algorithm outlining the treatment of patients with Bell palsy. CSF, Cerebral spinal fluid; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; MRI, magnetic resonance imaging.

Contributary. Valacyclovir, 1 g three times daily for 7 days, can be prescribed in conjunction with corticosteroids.

An eye shield or an eye patch should be worn during the night to prevent drying of the cornea. Liberal use of artificial tears during the day and an ophthalmic ointment such as Lacri-Lube at night should be prescribed to prevent drying of the cornea. Pain medication should be prescribed because the otalgia and cephalgia can be debilitatingly painful.

Prognosis

In a prospective study describing the spontaneous untreated course of idiopathic peripheral nerve palsy in patients with diabetes, 38% of patients had complete palsies, and only 25% regained normal facial muscle function. This is significantly worse than the observed rate of spontaneous full recovery in nondiabetic patients. Recurrence is rare (6.3%) and should prompt a work-up for other causes such as myasthenia gravis, lymphoma, sarcoidosis, Lyme disease, and rarely, Guillain-Barré syndrome.

Although the prognosis for recovery is good, the psychologic consequences can be long-lasting and are perhaps more significant than the physical disability. Patients report self-consciousness about the facial disfigurement, fear of permanent disfigurement, loss of self-esteem, and social ostracism.
otitis media, perforation of the tympanic membrane, and mass lesions.

CT lacks sensitivity in the evaluation of cranial nerve VIII disorders but may be useful in evaluating the bony temporal region. MRI with gadolinium enhancement is useful in identifying acoustic neuroma.

When a central cause is suspected because of abnormalities on cerebellar testing or clinical suspicion, MRI or magnetic resonance angiography (or both) should be performed to rule out a posterior circulation stroke as a central cause of the vertigo.

The differential diagnosis should include other cranial nerve deficits that are not typically present in benign causes of cranial nerve VIII dysfunction. Acoustic neuromas may compress the trigeminal nerve when they attain a size of 3 cm or greater; patients with complaints of facial numbness should therefore be evaluated for trigeminal neuropathy, as well for a mass lesion. Because large tumors can affect cranial nerves IX, X, and XI, these nerves should also be tested.

**Treatment**

Some patients who come to the emergency department with sudden or severe symptoms may not be able to comply with testing because the severity of the symptoms limits the ability to open their eyes and turn their head without experiencing nausea and vomiting or exacerbating the symptoms. In these cases it is appropriate to treat the patient symptomatically, initiate a work-up, and reassess clinically for improvement before attempting to move the patient or perform provocative testing.

**CRANIAL NERVE IX (GLOSSOPHARYNGEAL NERVE)**

**Anatomy**

The glossopharyngeal nerve provides branchial motor function to the stylopharyngeus muscle; visceral motor function to the otic ganglion and parotid gland; visceral sensory function from the carotid body; somatic sensory function to the posterior third of the tongue, the skin of the external ear, and the internal surface of the tympanic membrane; and the special sensory function of taste sensation from the posterior third of the tongue.

**Presenting Signs and Symptoms**

Patients with glossopharyngeal nerve palsy usually have associated symptoms involving other cranial nerves, most commonly cranial nerves X and XI. The most common symptoms are dysphagia and choking. If the vagus nerve is involved, the patient complains of hoarseness and demonstrates ipsilateral paralysis of the soft palate. Head, neck, and oral trauma or surgery can cause acute dysfunction of cranial nerve IX. Glossopharyngeal nerve palsy is a known complication of tonsillectomy surgery.33

Glossopharyngeal neuralgia is a rare disorder consisting of paroxysms of pain in the back of the throat and tongue. The pain is similar to that of trigeminal neuralgia in that the attacks are brief, lasting seconds to minutes. It is unilateral and usually triggered by chewing, swallowing, coughing, or sneezing.

**Treatment**

CT scanning is warranted to evaluate for a cerebrovascular event or tumor. Rarely, vasovagal syncope can result from bradycardia or asystole caused by vagus nerve cardioinhibitory input. Medical management is similar to that for trigeminal neuralgia. If involvement of other cranial nerves is evident on examination, the patient should be admitted for further evaluation and neurologic consultation.

**CRANIAL NERVE X (VAGUS NERVE)**

**Anatomy**

The vagus nerve is a mixed motor and sensory nerve that provides motor function to striated muscle of the pharynx, tongue, larynx, and tensor veli palatini, as well as motor function to smooth muscle and glands of the pharynx, larynx, and thoracic and abdominal viscera. Cranial nerve X provides general sensation from the skin at the back of the ear, the external auditory meatus, the pharynx, and part of the external surface of the tympanic membrane, as well as visceral sensation from the larynx, trachea, esophagus, and thoracic and abdominal viscera; from chemoreceptors in the aortic bodies; and from stretch receptors in the walls of the aortic arch.

**Presenting Signs and Symptoms**

Patients with palsies of the vagus nerve generally have hoarseness or difficulty swallowing. A history of recent carotid or thyroid surgery should prompt suspicion for a recurrent laryngeal nerve injury. The patient may also complain of regurgitation of food and liquid into the nose. Oropharyngeal examination usually reveals a drooped arch of the soft palate and uvular deviation away from the affected side.

**Treatment**

A CT scan of the head without contrast enhancement should be performed to evaluate for a cerebrovascular accident (hemorrhagic or ischemic) or skull-based lesions. Further inpatient evaluation may include MRI of the head and neck and work-ups for metabolic, infectious, or inflammatory disorders as warranted.

**CRANIAL NERVE XI (ACCESSORY NERVE)**

**Anatomy**

The accessory nerve provides motor function to the sternocleidomastoid and trapezius muscles.

**Presenting Signs and Symptoms**

Patients with accessory nerve palsies have neck and shoulder weakness on the affected side. Inspection may reveal a “dropped” shoulder—that is, the affected shoulder lying downward and in lateral rotation. Testing of the sternocleidomastoid reveals weakness when turning the head against resistance to the contralateral side. Because of the proximity of cranial nerves IX and X, particular attention should be paid to these nerve functions on examination. The most common causes are postoperative trauma (e.g., from cervical lymph node dissection) and a cerebrovascular accident.

**Treatment**

Treatment and disposition are similar to that for cranial nerves IX and X.
CRANIAL NERVE XII (HYPOGLOSSAL NERVE)

Anatomy

The hypoglossal nerve provides motor function to all the intrinsic tongue muscles and three of the four extrinsic tongue muscles: the genioglossus, styloglossus, and hypoglossus.

Presenting Signs and Symptoms

Patients with hypoglossal nerve palsies usually have unilateral tongue weakness.

Differential Diagnosis

The primary diagnostic consideration is distinguishing an upper from a lower motor neuron lesion. An upper motor neuron lesion causes contralateral tongue deviation and fasciculations, and tongue atrophy is absent. A lower motor neuron lesion causes ipsilateral tongue deviation and fasciculations, and tongue atrophy is present. A 26-year review of 100 cases of hypoglossal nerve palsy revealed that tumors, predominantly malignant ones, produced nearly half of the palsies. Only 15% of patients made a complete or nearly complete recovery.34 External lesions that cause compression or stretching of the nerve include internal carotid artery dissection or aneurysm, intracranial tumor, abscess, and other pharyngeal space tumors.

Treatment

Treatment and disposition are similar to that for cranial nerves IX, X, and XI. If there is concern for a cerebrovascular accident or space-occupying lesion, the patient should be admitted for evaluation.

Vertigo
Andrew K. Chang

KEY POINTS

- The majority of cases of vertigo arise from a peripheral source (e.g., cranial nerve VIII, vestibular structures) rather than a central source.
- The Dix-Hallpike test (also called the Nylan-Bárány test) can help confirm the diagnosis of benign paroxysmal positional vertigo.
- Other causes should always be considered because the signs and symptoms of central vertigo can mimic those of peripheral vertigo.
- Central vertigo should be suspected in patients with any abnormal neurologic findings.

PERIPHERAL VERTIGO

EPIDEMIOLOGY

GENERAL
Vertigo is diagnosed in roughly half of patients reporting dizziness. It is defined as the sensation of movement when none exists. About 80% of cases of vertigo are due to a peripheral lesion (pathology of the vestibular structures or cranial nerve VIII). Although peripheral vertigo is benign and not life-threatening, it may cause significant disability.

BENIGN PAROXYSMAL POSITIONAL VERTIGO
The most common type of vertigo is benign paroxysmal positional vertigo (BPPV).1 It occurs in all age groups but becomes more common with aging. Women are affected twice as often as men.

VESTIBULAR NEURITIS AND LABYRINTHITIS
These disorders most commonly occur in patients in the third to fifth decades of life. Peripheral vestibulopathies typically follow viral gastrointestinal or upper respiratory infections.

PATHOPHYSIOLOGY

Peripheral vertigo results from pathology involving the vestibular system or the eighth cranial nerve. The vestibular organs are responsible for equilibrium. The two main components—the three semicircular canals and the two otolith organs (utricle and saccule)—are interconnected and contain endolymph. The three semicircular canals—posterior (inferior), horizontal (lateral), and anterior (superior, vertical, dorsal)—are arranged at right angles to each other and allow detection of rotation via movement of endolymph. Otoliths (also known as otoconia), which are calcium carbonate particles, are found in the saclike utricle and provide information on head tilt.

When there is no disease and the head is held motionless, the bilateral vestibular systems fire at a tonic resting frequency. When the head rotates, there is increased firing from one semicircular canal and decreased firing from the others. The cerebral cortex interprets this information, synthesizes it with signals from the visual and proprioceptive systems, and translates it into the consciousness of movement. Vertigo results when the end-organs fire inappropriately at different frequencies, which causes unequal input to the brainstem and cerebral cortex.

Nystagmus is an involuntary rhythmic movement of the eyes to and fro that is often seen in patients with vertigo. Nystagmus is defined in terms of the direction of the fast-phase component. The factors listed in Table 96.1 should be noted in all patients with nystagmus. It should be kept in mind that on extremes of lateral gaze, several-beat nystagmus is a normal finding in 60% of patients.

BENIGN PAROXYSMAL POSITIONAL VERTIGO
BPPV results from a mechanical defect in the inner ear. Canalolithiasis is the most accepted hypothesis. According to this premise, the culprits are free-floating otoliths that have become displaced from the utricle and inappropriately enter and activate the end-organs of the semicircular canals.2 With certain head movements, a clump of otoliths moves, causes the endolymph to move with resultant inappropriate displacement of the cupula. Movement of the cupula triggers neural firing, with consequential vertigo and nystagmus. Less commonly, otoliths can adhere to the cupula and result in vertigo. This mechanism is called cupulolithiasis.

Although any semicircular canal can be affected, the posterior (inferior) canal is involved approximately 95% of the time because the otoliths, when displaced from the utricle, fall into the most dependent part of the system—the long arm of the posterior semicircular canal. BPPV is generally unilateral.
VESTIBULAR NEURITIS AND LABYRINTHITIS
Sometimes referred to as vestibular neuritis, vestibular neuritis occurs as a result of viral inflammation of the vestibular nerve. Unlike labyrinthitis, no auditory symptoms are present.

Labyrinthitis is caused by an infectious inflammation of the labyrinth. Viral causes are most common, although labyrinthitis may also occur as a result of Lyme neuroborreliosis or otosyphilis infections. Disruption of the round window by otitis media or cholesteatoma gives pathogens access to the labyrinth. Tumors, fistulas, meningitis, or mastoiditis may also create a portal of entry. Unilateral hearing loss and tinnitus of the affected ear is an early sign of labyrinthitis. Tumors, fistulas, meningitis, or mastoiditis may also occur as a result of Lyme neuroborreliosis or otosyphilis infections. Disruption of the round window by otitis media or cholesteatoma gives pathogens access to the labyrinth. Tumors, fistulas, meningitis, or mastoiditis may also create a portal of entry. Unilateral hearing loss and tinnitus of the affected ear is an early sign of labyrinthitis.

See Table 96.2 for the pathophysiology of other causes of peripheral vertigo.

PRESENTING SIGNS AND SYMPTOMS
Most patients describe vertigo as a spinning sensation (usually of the room or surrounding environment). In general, the emergency physician should ask open-ended questions when interviewing vertiginous patients because patients with dizziness are often very suggestible and will usually answer affirmatively to descriptions given to them. One should thus ask, “What do you mean by dizzy?” and not “Does the room spin?”

Diagnosis of peripheral vertigo is often based on the quality of the accompanying nystagmus. Peripheral nystagmus may be spontaneous or positional. In general, nystagmus is often provoked by having the patient lie with the affected ear dependent. With peripheral vertigo the nystagmus is generally fatigable—the symptoms and nystagmus decrease with repeated testing.

Details of the patient’s history, as well as findings on physical examination, can help narrow the differential diagnosis (Box 96.1).

**BOX 96.1 Evaluation of Vertiginous Patients**

Consider the following factors when questioning patients during emergency department evaluation:

**General**
- Sensation
- Length of each episode of vertigo
- Frequency of episodes
- Intermittent or constant
- Whether symptoms are mild, moderate, or severe

**Precipitating Factors**
- Noise
- Stress
- Head position
- Ameliorating circumstances
- Head or neck trauma
- Barotrauma (airplane flight, scuba diving)
- Ototoxic drugs (aspirin, aminoglycoside, loop diuretic)

**Symptoms**
- Do you tend to fall? Which side do you fall to?
- Any nausea or vomiting?
- Sensation of linear movement?

**Symptoms Associated with Central Vertigo**
- Diplopia
- Blurred vision
- Weakness of the arms or legs
- Numbness in the face or extremities
- Confusion or decreased consciousness
- Slurring of speech
- Clumsiness of the arms or legs
- Difficulty swallowing
- Associated headache
- Gait ataxia

**Symptoms Associated with Migraine**
- Photophobia
- Phonophobia
- Preceding aura

**Associated Auditory Symptoms**
- Hearing impaired in one or both ears
- Pressure in the ears
- History of ear infections
- Ear drainage
- Recent viral illness
- Tinnitus (constant or pulsatile)

**Associated Cardiac Symptoms**
- Chest pain
- Shortness of breath
- Palpitations
The diagnosis of BPPV is confirmed with the Dix-Hallpike test, also called the Nylan-Bárány test (Fig. 96.1; Box 96.2). The patient should sit on one end of the examination table so that the head hangs over the edge when lying down. Because visualization of the direction of nystagmus is important, the patient should be instructed to keep the eyes open during the test. The purpose of the Dix-Hallpike test is to determine whether otoliths are inappropriately placed in the labyrinth.

BENIGN PAROXYSMAL POSITIONAL VERTIGO

In BPPV, sudden transient vertigo is brought on by a change in head position. After head movement there is a delay of a few seconds, and then the room starts to spin and the patient experiences nausea or vomiting, or both. If the head is kept motionless, these symptoms typically resolve within 10 to 30 seconds. The symptoms are generally worse in the morning, probably because the otoliths have clumped together during sleep and exert a greater mass effect when the patient rolls over on awakening in the morning. The vertigo will tend to lessen as the day goes on because the otoliths become more dispersed and exert less of a mass effect.

The diagnosis of BPPV is confirmed with the Dix-Hallpike test, also called the Nylan-Bárány test (Fig. 96.1; Box 96.2). The patient should sit on one end of the examination table so that the head hangs over the edge when lying down. Because visualization of the direction of nystagmus is important, the patient should be instructed to keep the eyes open during the test. The purpose of the Dix-Hallpike test is to determine whether otoliths are inappropriately placed in the labyrinth.
posterior semicircular canal. Thus the goal is to try to move potential otoliths that are located in the posterior semicircular canal, which will elicit symptoms and nystagmus. The most provocative way to get otoliths to move is to first align the posterior canal in the same plane as the upcoming movement (lying supine). This is why the patient’s head, while sitting up, is first turned 45 degrees to the side being tested. The patient then lies back down so that the head overhangs the edge of the examination table. A positive test results in transient reproduction of the patient’s symptoms and transient torsional nystagmus in which the fast phase is upbeat (toward the forehead). The patient then sits up and the test is repeated with the head rotated 45 degrees to the opposite side. In general, the test should be positive with the head turned only to one side, and this becomes the starting side for the potentially curative Epley maneuver (to be discussed later).

Occasionally, the horizontal semicircular canal is affected, and this is diagnosed with the roll test. The patient lies supine (unlike the Hallpike test, the head does not need to extend off the edge of the examination table). The head is then turned to each side approximately 90 degrees. Reproduction of the symptoms and nystagmus should occur, with the fast phase of the nystagmus beating downward toward the dependent ear. The side that is involved is the one that has the more acute symptoms and more severe nystagmus.

### VESTIBULAR NEURITIS AND LABYRINTHITIS
Spontaneous vertigo develops over a period of hours. Nausea and vomiting may occur. Symptoms that accompany a viral illness may also be present. The vertigo is initially severe, may require 1 or 2 days of bed rest, and then gradually resolves over a few weeks.

Spontaneous nystagmus with peripheral features may be seen on examination. Postural imbalance with a tendency to fall toward the side with the lesion is also seen. Middle ear infection or serous fluid may be present. Patients have a positive head-thrust test, also known as the head impulse test.

The head-thrust test begins by directing the patient to look straight ahead. The examiner then places both hands on the patient’s head and rapidly thrusts the patient’s head to one side approximately 10 degrees. Normally, the patient’s eyes will remain focused straight ahead when the head is turned rapidly. In patients with unilateral peripheral vestibular loss, such as occurs with vestibular neuritis and labyrinthitis, the eyes will move with the head but then a corrective saccade will bring the eyes back to the midline. Visualization of a corrective saccade (a positive test) confirms the diagnosis. Both sides should be tested.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

### COMPUTED TOMOGRAPHY
Because skull-related artifacts are common with computed tomography, it has limited utility for evaluating the posterior fossa. If a patient has a focal neurologic finding and normal results on computed tomography, further imaging is necessary.

### MAGNETIC RESONANCE IMAGING AND MAGNETIC RESONANCE ANGIOGRAPHY
For assessment of pathologic causes of vertigo, magnetic resonance imaging (MRI) is the modality of choice. Magnetic resonance angiography is a noninvasive technique that can be used to visualize the vessels of the posterior circulation. It can detect aneurysms, atherosclerosis, dissections, vasculitis, thrombosis, and other processes.

### LABORATORY TESTING
Laboratory testing is rarely useful in the initial evaluation of a vertiginous patient. Screening tests include hematocrit, glucose, and electrolyte levels.
ELECTROCARDIOGRAPHY
An electrocardiogram is useful to evaluate for signs of cardiac ischemia or dysrhythmia.

TREATMENT
Short-term treatment with vestibular suppressants is useful in the management of peripheral vertigo (Table 96.4). The sensory conflict theory states that a mismatch of information from vestibular, visual, or proprioceptive input will temporarily result in nausea and vertigo but will resolve as habituation occurs. This mechanism occurs via γ-aminobutyric acid, acetylcholine, serotonin, and histamine receptors. In the emergency department (ED) setting, parenteral antiemetics such as benzodiazepines (e.g., valium, 2 to 5 mg intravenously), promethazine, and ondansetron are generally most helpful. Note that the Food and Drug Administration recently recommended that promethazine be administered only via the intramuscular route when given parenterally.

Vestibular exercises such as Brandt-Daroff exercises may be helpful for BPPV, poorly compensated vestibular neuritis, end-stage Meniere disease, and chronic and psychiatric vertigo. These exercises, which can be performed in the physical therapy unit or at home, are based on the concept of fatigue and facilitation of central compensatory mechanisms.

BENIGN PAROXYSMAL POSITIONAL VERTIGO
The Epley maneuver takes approximately 3 minutes and has been shown to be safe and effective in treating posterior canal BPPV. It is also easily performed in the ED setting. Gravity is used to move the otoliths out of the posterior semicircular canal into the utricle, where they will no longer cause vertigo.

The starting position of the Epley maneuver is determined by the diagnostic Hallpike test (recall that only one side should be positive). As in the Hallpike test, the patient sits upright with the head turned 45 degrees to the affected side and then lies down with the head overhanging the edge of the examination table. This maneuver should cause reproduction of the symptoms and torsional nystagmus.

Next, the head is rotated 90 degrees to the opposite side while it remains overhanging the edge of the examination table. The patient now rolls over onto the side and turns the head toward the ground. The patient is instructed to not lift the head up while turning onto the side. The patient is then brought up to the sitting position (the legs can hang over the side of the examination table or return to the original starting position), and the head is brought forward slightly. Each position is held for approximately 30 seconds or until the symptoms and nystagmus resolve. It is currently recommended that the patient remain upright at least 20 minutes after the maneuver, which may be sufficient time for the otoliths to reattach to hair cells in the utricle (Fig. 96.2).

The Semont liberatory maneuver can also be used to treat BPPV. The patient sits upright in the middle of the examining table with his legs overhanging the edge of the gurney. The head is turned 45 degrees to the side opposite the involved canal. The patient is then rapidly laid down sideways to the side opposite of the direction his head is turned. Then the patient is rapidly laid down sideways to the other side, such that the patient’s face is now directed toward the gurney. The patient then returns to the sitting position. The author does not recommend the use of this maneuver because the rapid movements are not likely to be tolerated, especially by elderly patients.

Patients with a positive roll test (indicating horizontal semicircular canal involvement) can be treated with the barbeque roll maneuver in which the patient is placed in the supine position with the head turned 90 degrees to the affected side...
as determined by the roll test. The head is then turned in 90-degree intervals in the opposite direction back to the original starting position. This requires the patient to eventually turn onto the abdomen. Each position is held for 30 seconds or until resolution of the vertigo and nystagmus. Anterior canal BPPV is diagnosed by a characteristic history, as well as by downbeat torsional nystagmus during the Dix-Hallpike test. Because downbeat (fast phase beating toward the feet) nystagmus can also indicate a central cause of vertigo and anterior canal involvement is extremely rare, the author cautions against making this diagnosis and recommends consideration of a central cause of vertigo.

**VESTIBULAR NEURITIS AND LABYRINTHITIS**

A recent multicenter trial sought to treat vestibular neuritis in a manner similar to Bell palsy. The study found that a 22-day taper of methylprednisolone was beneficial but that valacyclovir was not.8

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Once the symptoms are controlled, patients with peripheral vertigo can be discharged from the ED with meclizine as needed. Arrangements for follow-up should be made with the primary care physician and, if needed, a specialist. Peripheral vertigo is typically self-limited, although its duration is variable. Fixed unilateral lesions may produce steady symptoms that eventually diminish as a result of habituation and compensatory mechanisms by the central nervous system (CNS), although this process can take several weeks or months.

**BENIGN PAROXYSMAL POSITIONAL VERTIGO**

BPPV is generally self-limited but recurs up to 50% of the time.7 Persistent or recurrent vertigo is managed with the maneuvers described previously. Vestibular suppressants may also be prescribed.

Patients who work at heights (builders, roofers) should curtail activities until their symptoms have resolved. All patients can benefit from specialist referral. Outpatient contrast-enhanced MRI may be used to look for an acoustic neuroma or other pathology that can mimic BPPV.

In some intractable incapacitating cases, patients may benefit from neurectomy or nonampullary plugging of the semicircular canal.9

**CENTRAL VERTIGO**

Central vertigo occurs as a result of disorders of the CNS. Major causes of central vertigo are listed in Box 96.3. Migraine and stroke are emphasized in the rest of this section.

**EPIDEMIOLOGY**

**MIGRAINE**

The lifetime prevalence of migraine (16%) and vertigo (7%) leads to an expected comorbidity of the two conditions in 1.1% of the general population.10 A recent German survey, however, found a prevalence of 3.2%.11 Vestibular migraines are the most common cause of central vertigo and occur in 25% of patients suffering from migraines. Vestibular migraines tend to occur in women between the third and fifth decades of life.

STROKE
Each year 795,000 people suffer a new or repeated stroke, and stroke remains the third leading cause of death in the United States. Twenty percent of strokes involve the posterior circulation, which can affect the vestibular structures or pathways leading to vertigo.

PATHOPHYSIOLOGY
Central vertigo is caused by disorders of the CNS. The visual, proprioceptive, and vestibular systems inform the brain about movement and location of the body. Input from these systems is integrated by the CNS, and any mismatch in information leads to vertigo. Overlapping of these systems allows two of them to compensate when one is deficient.

MIGRAINE
It has been theorized that the increased sensitivity to vestibular input in patients with vestibular migraine is analogous to the increased sensitivity causing photophobia and phonophobia in patients with typical migraines.

STROKE
The CNS obtains its blood supply from the carotid and vertebral arteries. The carotid arteries are referred to as the anterior circulation and the vertebral arteries as the posterior circulation. These two arterial systems join at the base of the brain in the vascular circle of Willis. Smaller arteries branch off from this anastomosis to supply specific areas of the brain. Blockage of one of these arteries results in a recognizable pattern of signs and symptoms consistent with the brain territory affected. A stroke is caused by thrombosis, hemorrhage, or embolism in one of the cerebral arteries. Vertigo secondary to stroke generally indicates involvement of the posterior circulation.

OTHER
The pathophysiology of selected other causes of central vertigo are listed in Box 96.4.

PRESENTING SIGNS AND SYMPTOMS
The most important clue to the diagnosis of central vertigo is the presence of associated neurologic signs and symptoms. Symptoms may occur insidiously with a slow-growing lesion such as a tumor or rapidly from stroke, intracranial hemorrhage, or trauma. In general, central vertigo is not positional, its intensity is mild, and there is no associated diaphoresis, nausea, vomiting, tinnitus, or hearing abnormality. It is important to note that these clues are generalizations with many published exceptions.

MIGRAINE
If a preceding aura occurs, the migraine will usually develop over a period of minutes and subside within an hour. This is followed by the acute onset of vertigo. Patients usually have an associated headache; however, vertigo may be the headache equivalent. Fluctuating low-frequency hearing loss and tinnitus can also occur (Box 96.5).

STROKE
Twenty percent of strokes involve the posterior circulation, which can affect the vestibular structures or pathways leading to vertigo. Symptoms of stroke vary depending on the affected anatomy and vasculature but often involve one or more of the “five D’s”: dizziness, diplopia, dysarthria, dysphagia, and dystaxia. The vascular structures most commonly affected by stroke and other lesions can be divided into anatomic territories, including the vertebrobasilar territory, the

---

**Box 96.4 Pathophysiology of Other Causes of Central Vertigo**

- Lateral medullary syndrome (Wallenberg syndrome): ipsilateral ischemia (usually from the posterior inferior cerebellar artery or one of its branches) or rarely demyelination of the lower brainstem. Cranial nerves IX and X are most commonly affected.
- Subclavian steal syndrome: occurs when blood is siphoned away from the central circulation to the left upper extremity, which leads to ischemia of the posterior circulation.
- Rotational vertebral artery occlusion syndrome: turning of the head may cause occlusion of the vertebral artery at the C1-C2 level.
- Vertebral artery dissection: sudden strain of the neck and even trivial injuries can cause dissection, which leads to ischemia of the posterior circulation. Blood penetrates the arterial wall and compresses the lumen or forms an aneurysmal dilation. Small emboli and subarachnoid hemorrhages may also occur.

**Box 96.5 Findings Associated with a Migrainous Etiology of Vertigo**

- Onset early in life
- Female gender
- Occurring during menses
- Episodic vertigo
- Spontaneous or positional vertigo
- Episodes lasting no more than a few days
- Frequent recurrences within a year
- Interferes with daily activities
- History of motion sickness as a child
- Hearing loss
- Symptoms associated with the vertigo
  - Migrainous headache
  - Photophobia
  - Aura (visual, vertiginous)
  - Phonophobia

- Migraine medications terminating the symptoms
- Other causes of vertigo ruled out
- At least two attacks
superior cerebellar artery territory, and the posterior inferior cerebellar artery territory (see Table 96.5).

The hallmark of many brainstem strokes is crossed signs (e.g., contralateral sensory and motor findings). Vertigo and nystagmus occur early in the progression of ischemia. Dysarthria and oculomotor deficits develop later in the course and portend major neurologic catastrophe.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

**MIGRAINE**

MRI may be performed to evaluate for a cerebellar or brainstem lesion if suspected.

*AICA, Anterior inferior cerebellar artery territory; B, bilateral; C, contralateral; I, ipsilateral; MMI, medial medullary infarction; PICA, posterior inferior cerebellar artery territory (Wallenberg, lateral medullary); SCA, superior cerebellar artery territory; U, unilateral; VBAT, vertebral basilar artery thrombosis; VBI, vertebrobasilar insufficiency.*
STROKE
Although computed tomography may show large bleeding, MRI is best for imaging the posterior fossa.

Acute posterior circulation infarcts are best seen on diffusion-weighted MRI. Magnetic resonance angiography is used to additionally assess the vertebral arteries. Patients with contraindications to MRI should undergo computed tomography and computed tomographic angiography. Carotid ultrasound scanning is not helpful in patients with posterior ischemia. Electrocardiography, echocardiography, and rhythm monitoring are important in evaluating cardiac and aortic sources of embolism.

TREATMENT
Causes of central vertigo are serious and appropriate consultation should be obtained. Although compensation may occur with peripheral lesions, the CNS has relatively less plasticity and diminished capacity for compensation over time.

MIGRAINE
Information on specific treatment of vertiginous migraines is limited (e.g., patients should avoid migraine triggers) and is not based on controlled studies. Patients should be referred to a neurologist for follow-up.

STROKE
Although intravenous tissue plasminogen activator (t-PA) may enhance recovery if given within 3 hours of the onset of ischemic stroke, mixed results are found when t-PA is used for vertebrobasilar disease.13

OTHER
Ventriculostomy and occipital craniotomy are often performed to relieve pressure within the posterior fossa associated with hemorrhage or a mass effect. Administration of mannitol should be considered for patients with signs of herniation.

Hypotension should be corrected because it worsens symptoms and outcome. Intravenous fluids, blood, and pressors should be administered as needed. Neurologic consultation may be useful to guide treatment.

REFERENCES

Peripheral nerve disorders can result in varied findings, including proximal or distal weakness, symmetric or asymmetric symptoms, and acute or chronic manifestations. Motor symptoms range from weakness to paralysis, whereas sensory symptoms range from numbness to pain.

Evaluation of peripheral nerve disorders requires an understanding of the anatomy of the spinal cord and the peripheral nervous system (Fig. 97.1). The peripheral nervous system is composed of 12 cranial nerves and 31 spinal nerves. Spinal nerves are formed from motor fibers whose cell bodies reside in the ventral horn of the spinal cord and from sensory fibers whose cell bodies are found in the dorsal root ganglion. The motor and sensory fibers join to form one nerve as it exits the spinal canal. Spinal nerves from several spinal levels merge at the cervical, brachial, lumbar, and sacral plexuses. Peripheral nerves originate either at these plexuses or, if they are formed from nerves of only one spinal level, as they exit the vertebral foramina.

Peripheral nerves consist of mixed fibers with variable amounts of motor, sensory, and autonomic fibers; small and large fibers; and myelinated and unmyelinated fibers. These fibers, which are surrounded by endoneurial fluid and covered in perineurium, form fascicles that are bundled together by the epineurial sheath. This sheath forms a protective barrier akin to the blood-brain barrier in the central nervous system.

In patients with symptoms concerning for a peripheral nerve disorder, the history and physical examination are important in localizing the lesion. Spinal nerve, or nerve root, lesions are called radiculopathies and result in myotomal weakness or dermatomal sensory loss. Plexus lesions can be variable, with symptoms that cross myotomes and dermatomes or involve multiple peripheral nerves. Symptoms depend on which trunk or cord is involved. Peripheral nerve lesions cause weakness and sensory loss that is limited to a specific peripheral nerve.

Systemic diseases affect the peripheral nervous system as well, and multiple peripheral nerves may be involved. Examples include disorders of the neuromuscular junction (NMJ), demyelinating disorders, diabetes, and toxic effects of drugs or chemicals (Box 97.1).

Nerve compression is the most common cause of radiculopathy and mononeuropathy.
Radiculopathy and radicular pain are typically associated with symptoms within a dermatome or myotome.
Patients with mononeuropathy have symptoms limited to a single peripheral nerve.
Guillain-Barré syndrome is an autoimmune demyelinating disease that results in primarily motor symptoms, with severe disease leading to respiratory compromise.
Myasthenia gravis and Lambert-Eaton myasthenic syndrome are both autoimmune disorders of the neuromuscular junction; myasthenia gravis affects the postsynaptic membrane, whereas Lambert-Eaton syndrome affects the presynaptic membrane.
Botulism is a toxin-mediated disorder of the neuromuscular junction.
Systemic diseases such as diabetes mellitus and human immunodeficiency virus infection can result in several peripheral nerve disorders.

Spinal nerve compression results in radiculopathy, radicular pain, or both. Radiculopathy is due to blocked conduction along a spinal nerve and results in a neurologic deficit: dermatomal sensory loss or myotomal weakness. Radicular pain is due to irritation or inflammation of the spinal nerve, neurologic deficits are absent, and patients have purely painful symptoms that may not be isolated to a dermatome.
Causes of spinal nerve compression are varied; if a patient is younger than 50 years, the symptoms are more likely to be caused by disk herniation, and if older than 50 years, by degenerative changes.

### PRESENTING SIGNS AND SYMPTOMS

As noted, sensory loss and weakness follow a dermatomal or myotomal distribution. Diminished reflexes may also assist in determining the nerve root that is involved (Table 97.1).

In the cervical region, C6 and C7 are the most commonly affected, with higher roots less frequently involved. This is true for the lumbosacral spinal nerves as well, with more patients having signs in the L5-S1 distribution. Sciatica is a particularly common syndrome of radicular pain and involves more than one of the L2-S1 spinal nerves.

### DIAGNOSTIC TESTING

A careful history and physical examination will help localize the symptoms of a radiculopathy. The straight leg raise should be used to test for lumbosacral involvement. While the patient is lying supine, the leg is raised with the knee in extension. The test is considered positive for spinal nerve involvement when symptoms are reproduced within 60 degrees of elevation.

If a patient has solely radicular pain, imaging may not be necessary because the symptoms resolve in 60% to 80% of patients within 6 to 12 weeks with conservative treatment. In patients whose symptoms fail to resolve, progress, or involve sensory loss or weakness, either computed tomography or magnetic resonance imaging (MRI) is indicated. Patients should also undergo imaging if they have a history of malignancy, long-term steroid use, human immunodeficiency virus (HIV) infection, diabetes, acute loss of neurologic function, or known trauma. In general, MRI is preferred because it has higher soft tissue resolution. For disk disease, it is important to note that the size of a disk herniation does not always correlate with clinical symptoms: patients without evidence of herniation may have significant symptoms, whereas patients with an incidental finding of disk herniation may have no symptoms.

### TREATMENT

In the acute phase of injury, painful symptoms are typically treated conservatively with nonsteroidal antiinflammatory...
Mononeuropathies

Epidemiology

As with radiculopathy, compression of peripheral nerves is the most common cause of peripheral mononeuropathy, the most frequent being median mononeuropathy (Fig. 97.2). Women older than 55 years are most commonly affected, with a 4.6% prevalence in women and 2.8% in men. The second most frequent cause is ulnar mononeuropathy; specifically, cubital tunnel syndrome. Other common peripheral mononeuropathies include involvement of the radial nerve in the upper extremity and the peroneal and lateral cutaneous femoral nerves in the lower extremity.

Pathophysiology, Presenting Signs and Symptoms, and Diagnostic Testing

For mononeuropathies, the history and physical examination largely lead to the appropriate diagnosis. Findings in patients with common mononeuropathies and diagnostic maneuvers are presented in Table 97.2.6-12 In patients with a history of trauma or acute symptoms, plain films may be necessary to rule out fracture or dislocation. Patients with subacute or chronic symptoms should be asked about chronic conditions. Mononeuropathies can occur with several systemic diseases, including diabetes mellitus, amyloidosis, HIV, and states that cause edema, such as pregnancy.13 Outpatient testing may be more appropriate for individuals with chronic symptoms. MRI or electrodagnostic testing such as electromyography or nerve conduction studies may be necessary, and the patient should be referred to a neurologist. MRI may demonstrate chronic nerve injury, whereas electrodagnostic testing may show slowing of nerve conduction. These studies may aid in deciding whether surgical repair or decompression is necessary for certain syndromes.

TREATMENT

Primary treatment should be aimed at the precipitating event for both acute and chronic mononeuropathy.

With acute mononeuropathy, the primary cause of injury is generally trauma. Fractures and dislocations should be reduced appropriately and immobilized with the guidance of surgical consultation.

Initial treatment of chronic mononeuropathy is typically conservative and supportive. Modification of behavior is a key component of treatment and prevention of further injury. For carpal tunnel syndrome, behavior modification includes weight loss and avoidance of caffeine, nicotine, and alcohol. Patients should be instructed to decrease any possible trauma related to repetitive use by making changes in workplace ergonomics, reducing repetitive use, and changing posture. Some neuropathies may require supportive devices; for example, the carpal tunnel may benefit from wearing a wrist splint, the ulnar nerve from wearing a sling or a long arm posterior splint, the radial nerve from wearing a volar splint, and the peroneal nerve from wearing a posterior splint.8,9 NSAIDs are typically prescribed for relief of symptoms, although they may be ineffective without appropriate
behavioral modification. In patients with a systemic disease, the primary process should be treated. Diuretics may be given if edema is believed to be contributing significantly to the patient’s symptoms. More invasive procedures, such as local nerve block for meralgia paresthetica or surgical decompression for carpal tunnel syndrome, are reserved for severe cases.

**CHAPTER 97 PERIPHERAL NERVE DISORDERS**

**Autoimmune Disorders**

**GUILLAIN-BARRÉ SYNDROME**

**EPIDEMIOLOGY**

Guillain-Barré syndrome (GBS) is also known as acute inflammatory demyelinating polyradiculopathy or Landry-Guillain-Barré syndrome. Its worldwide incidence is 0.6 to 4 per 100,000 individuals annually. 14

**PATHOPHYSIOLOGY**

GBS is characterized by immune-mediated destruction of the myelin sheath of peripheral nerves. Biopsy frequently reveals a mononuclear inflammatory infiltrate. Although its exact etiology remains unknown, two thirds of cases are preceded by an infection. Associations have been made with viral or febrile illness, *Campylobacter jejuni* infection, vaccinations, and even surgery or trauma.

GBS is a monophasic illness with progressive symptoms that reach a nadir in 2 to 4 weeks. Recovery can vary from weeks to a year. Mortality has been reported in 4% to 15% of patients, whereas another 10% to 20% have significant residual motor dysfunction.

**PRESENTING SIGNS AND SYMPTOMS**

**CLASSIC GUILLAIN-BARRÉ SYNDROME**

Classic GBS is preceded by a viral prodrome and followed by acute or subacute ascending symmetric weakness or paralysis and loss of the deep tendon reflexes. Paralysis may ascend to the diaphragm and compromise respiratory function to the extent that mechanical ventilation is required. One third of patients will require intubation and 15% will experience dysautonomia. Specific findings are strongly suggestive of this diagnosis (Box 97.2).

**VARIANTS OF GUILLAIN-BARRÉ SYNDROME**

**Acute Motor Axonal Neuropathy**

This purely motor form of GBS is associated with *C. jejuni* infection and is more often preceded by diarrhea than by a viral prodrome. It results in axonal injury rather than demyelination.

**Acute Motor and Sensory Axonal Neuropathy**

This variant involves loss of both motor and sensory function. As with acute motor axonal neuropathy, electrodiagnostic testing reveals axonal degeneration.

**Miller-Fisher Syndrome**

Identified in 1956, Miller-Fisher syndrome is characterized by ophthalmoplegia, ataxia, and decreased or absent reflexes. Patients have significantly less weakness and a milder course than do those with classic GBS.

**DIAGNOSTIC TESTING**

It is critical that respiratory function be assessed early and often because maintenance of airway protection well in advance of respiratory compromise decreases the incidence of aspiration and other complications of emergency intubation (Box 97.3). The most studied monitoring parameter is vital capacity (VC), with normal values ranging from 60 to 70 mL/kg. However, a simple bedside assessment of respiratory status can be obtained by having the patient count from 1 to 25 with a single breath and trending the values over time.

If the patient’s condition does not initially meet the criteria for intubation, VC should be monitored closely—every hour for the first 4 hours and then every 4 hours. 15

Lumbar puncture often reveals the classic “albuminocytologic dissociation” in which cerebrospinal fluid (CSF) protein is high without pleocytosis. The protein level is greater than 45 mg/dL. Cell counts are typically below 10/mL and usually

**BOX 97.2 Findings Suggesting Guillain-Barré Syndrome**

- Relative symmetry of symptoms
- Mild sensory signs and symptoms
- Cranial nerve involvement
- Autonomic dysfunction
- Absence of fever at onset
- Cytoalbuminologic dissociation of cerebrospinal fluid
- Typical electrodiagnostic findings
- Progression over days to weeks
- Recovery beginning 2 to 4 weeks after cessation of progression

**BOX 97.3 Indications for Intubation in Patients with Guillain-Barré Syndrome**

- Rapid progression of respiratory compromise
- Vital capacity less than 20 mL/kg
- Negative inspiratory force less than −30 cm H$_2$O
- Greater than a 30% decrease in either vital capacity or negative inspiratory force in the first 24 hours
- Autonomic instability
consist predominantly of mononuclear cells. Up to 80% of patients demonstrate this classic pattern. Of note, CSF studies are more likely to be negative in the first week of illness. With counts higher than 100 cells/mL, other causes should be considered, including HIV infection, Lyme disease, syphilis, sarcoid, tuberculosis, bacterial meningitis, leukemic infiltration, and central nervous system vasculitis.

Electrodiagnostic testing confirms the demyelination typical of GBS. In patients with the acute motor axonal neuropathy or acute motor and sensory axonal neuropathy variants, electromyography and nerve conduction studies reveal axonal injury rather than demyelination.

**TREATMENT**

The first priority in the treatment of patients with GBS is airway management. Along with frequent assessment of the need for intubation, early consultation with neurology or critical care specialists (or both) will ensure a coordinated management strategy.

Corticosteroids have shown no benefit in the management of GBS and may be harmful. The two modalities that have clearly proved to be beneficial are intravenous immunoglobulin (IVIG) and plasmapheresis. Both provide an equal, but not additive reduction in the duration of symptoms if given within 2 weeks of onset to ambulatory patients and within 4 weeks to nonambulatory patients. Plasmapheresis has been associated with more treatment complications and adverse events, including hemodynamic instability, which has resulted in a higher rate of discontinuation. However, it is also associated with a lower relapse rate. Overall, fewer complications occur with IVIG, although thromboembolism and aseptic meningitis have been reported.16

The decision to admit the patient to the hospital should be made in consultation with a neurologist and may be based on clinical criteria alone or confirmation by CSF analysis and nerve conduction studies. Patients who require or may require intubation, are unable to ambulate, or are being considered for plasmapheresis should be admitted to the intensive care unit.

**MYASTHENIA GRAVIS**

**EPIDEMIOLOGY**

Myasthenia gravis has a prevalence of 50 to 125 individuals per million. The age at onset is bimodal: the first peak involves persons in their 20s to 30s, with women being affected more than men, and the second peak occurs during the sixth and seventh decades, with men being affected more than women.

**PATHOPHYSIOLOGY**

Myasthenia gravis has many causes, but they all lead to the formation of autoantibodies directed against nicotinic acetylcholine receptors (AChRs) at the NMJ (Fig. 97.3). This results in autoimmune destruction of AChRs through complement-mediated destruction, as well as increased endocytosis by muscle cells. The autoantibodies further compete with acetylcholine (ACh) for binding at the remaining receptors. Thus with repeated stimulation of the same muscle, fewer and fewer sites are available and fatigue develops.

**PRESENTING SIGNS AND SYMPTOMS**

**NEW ONSET**

Muscular weakness and fatigability are the hallmarks of myasthenia gravis. When patients are seen in the emergency department (ED) with an initial manifestation of the disease, the symptoms usually consist of mononeuropathy involving the ocular or bulbar muscles. The typical finding is ptosis, diplopia, or blurred vision. Ocular muscle weakness may be the first sign in up to 40% of patients, although it will develop in 85% in due course. When present, ptosis is often worse toward the end of the day. When the bulbar muscles are involved, dysarthria or dysphagia occurs. Respiratory failure is a rare initial sign. Nevertheless, up to 17% of patients may have weakness of the muscles of respiration.
Acute myasthenic crisis is defined as respiratory failure eventually requiring mechanical ventilation. It occurs in 15% to 20% of patients, generally within the first 2 years of the disease. With the use of better and more aggressive techniques in the intensive care unit, mortality has declined tremendously.

Underlying infection, aspiration, and changes in medications most often trigger myasthenic crisis, but the precipitant may not be found in up to 30% of cases (Box 97.4). Some patients experience an increase in weakness when starting chronic steroid therapy. Other precipitants include surgery and pregnancy.

As with GBS, the initial step in managing patients in myasthenic crisis is assessing respiratory status and securing the airway, if necessary. A patient who is complaining of shortness of breath or difficulty breathing should have VC measured frequently. In contrast to the steady deterioration associated with GBS, patients in myasthenic crisis may have fluctuating weakness. In these patients a lower VC of 15 mL/kg is considered an indication for intubation, but the trend of their respiratory function is more useful than a single measurement.

Approximately 12% of pregnant women with myasthenia gravis will give birth to symptomatic infants because of placental transfer of autoantibodies. An infant’s symptoms develop within 2 days of life and include impaired sucking, weak cry, limp limbs, and rarely, respiratory insufficiency. The symptoms disappear within days or weeks as antibody titers diminish. In severe cases of respiratory failure, intubation is necessary, and exchange transfusion should be considered.

The diagnosis is based on clinical findings, bedside testing, and serologic studies.

The edrophonium test is a pharmacologic test involving the use of a short-acting acetylcholinesterase (AChE)-blocking agent that can be done at the patient’s bedside. The test confirms the diagnosis of myasthenia if the ptosis improves after the intravenous administration of edrophonium. An initial dose of 1 mg is given and the patient is observed for an adverse reaction or improvement in the symptoms of ptosis, medial rectus weakness, or dysphonia. If unimproved in 30 to 90 seconds, a second dose of 3 mg is given. Another 3-mg dose of edrophonium is administered if no response is seen after 30 to 60 seconds. If there is still no response, a final dose of 3 mg is given, for a total maximum dosage of 10 mg. Edrophonium may result in a severe anticholinergic reaction, especially in the elderly, cardiac disease patients, those with chronic obstructive pulmonary disease, or asthmatics. Symptoms include salivation and gastrointestinal cramping but may be more severe, such as bradycardia, bronchorrhea, bronchospasm, and worsening weakness. Because of the potential for bradycardia, atropine should be at the bedside during edrophonium testing.

The ice test is another bedside test that can be used to quickly confirm the diagnosis. Cooling decreases the symptoms of myasthenia gravis, whereas heat exacerbates them. In this test the distance between the upper and lower lids is measured before the application of an ice pack for 2 to 3 minutes to the most severely affected eye.

Receptor antibody testing is positive in 80% to 90% of patients. Many patients found to be seronegative nonetheless respond to traditional therapy aimed at lowering levels of circulating antibodies, thus suggesting that antibodies are present but not detected.

AChE inhibitors such as pyridostigmine and neostigmine are the backbone of outpatient chronic therapy and provide symptomatic improvement. This class of drugs inhibits the hydrolysis of ACh, which leads to an increased circulating concentration of ACh to compete with the antibody for AChR binding sites. The most common side effects are those of excessive cholinergic stimulation as mentioned earlier. These drugs are not directed at the underlying immunologic basis of the disease and are often used as adjunctive therapy to control symptoms while allowing time for other therapy to take effect, after which they are discontinued.

The use of intravenous pyridostigmine in the setting of acute exacerbation of myasthenia gravis is controversial. Some evidence indicates that its use may complicate ventilation by worsening pulmonary secretions. Consequently, cholinergic drug therapy should be discontinued during a myasthenic crisis. In addition, a cholinergic crisis characterized by acute decompensation and excessive muscarinic stimulation may be caused by excessive medication with AChE inhibitors. Cholinergic crisis should be distinguished from an exacerbation of the disease by muscarinic findings on physical examination: excessive sweating, salivation, lacrimation, miosis, tachycardia, and gastrointestinal hyperactivity.

Immunosuppressant drugs are often used for chronic control of the symptoms of myasthenia gravis. They have no role in the acute management of myasthenic crisis, although they may be started before extubation of patients recovering from...
a crisis. Corticosteroids, azathioprine, and cyclosporine have all been used.

**THYMECTOMY**
Thymectomy in otherwise well patients between adolescence and 60 years of age results in remission or improvement in up to 50% of cases. However, the onset of improvement after thymectomy is often delayed for 2 to 5 years.

**IMMUNOMODULATORY THERAPY**
Plasmapheresis and IVIG are reserved for patients with severe exacerbations or are administered preoperatively to patients with stable myasthenia gravis. Of patients treated with IVIG, 50% to 90% have some improvement following infusion. These treatment modalities should be administered in conjunction with a neurologist.

**LAMBERT-EATON MYASTHENIC SYNDROME**

**EPIEDEMOIOLOGY**
Lambert-Eaton myasthenic syndrome (LEMS) is relatively uncommon, with a prevalence of 1 in 100,000 individuals. The disease occurs predominantly in those older than 50 years, with both genders affected equally.

**PATHOPHYSIOLOGY**
In healthy presynaptic neurons, depolarization opens channels that allow calcium to enter. This results in ACh-filled vesicles fusing with the presynaptic membrane and release of ACh into the synapse. ACh then stimulates the postsynaptic neuron, which results in transmission of the impulse from one neuron to the next.

LEMS is an autoimmune presynaptic disorder of the NMJ. IgG autoantibodies bind to the presynaptic calcium channels, thereby inhibiting entry of calcium into the cell during depolarization. The net effect is decreased release of ACh and absent or diminished transduction of signal to the postsynaptic membrane. This disease affects not only the NMJ but also muscarinic receptors and results in autonomic dysfunction.

Frequently, this disease is associated with other pathology. Malignancies are often seen with LEMS, with upward of 70% of cases having a concomitant malignancy. The most common association is with small cell lung cancer: 62% of cases have this link. Diagnosis of the malignancy may come after the diagnosis of LEMS. Because LEMS is an autoimmune disorder, it is also associated with other autoimmune disorders, including hypothyroidism, pernicious anemia, and celiac disease.

**PRESENTING SIGNS AND SYMPTOMS**
The typical symptoms involve weakness of the proximal muscles, with the lower extremities being affected more than the upper ones, and decreased or absent reflexes. Bulbar symptoms may be present, though with significantly less frequency and severity than in myasthenia gravis. Autonomic symptoms are reported in 75% of patients; symptoms include dry eyes and mouth, impotence, constipation, and orthostatic hypotension.

Patients often have symptoms of weakness with minimal associated disability; the symptoms frequently improve with repetitive use because calcium is able to accumulate in the presynaptic neuron. This is demonstrated with the Lambert sign, in which there is a progressive increase in grip when maintained over a few seconds. It can also be seen in reflexes, which improve after exercising the muscle.

**DIAGNOSTIC TESTING**
Testing specific to this disease is typically not conducted in the ED, and a neurologist should be consulted for evaluation. Antibody testing is positive in 85% of patients. LEMS may develop up to 2 years before the diagnosis of a malignancy, and therefore patients should be evaluated for malignancy.

**TREATMENT**
The most effective treatment of LEMS involves treatment of the primary malignancy if present. Other treatments have been used over the years, including immunosuppressants such as prednisone, pyridostigmine (AChE inhibitor), plasma exchange, IVIG, and 3,4-diaminopyridine (3,4-DAP). 3,4-DAP is an oral medication that blocks potassium channels and prevents repolarization and removal of calcium from the cell. Evidence for the efficacy of these therapies is limited because the disease itself is uncommon, although randomized controlled trials have found improvement with IVIG and 3,4-DAP.
produced by *C. botulinum* cause human disease: toxin types A, B, and E. Most cases of botulism are isolated events associated with improperly preserved canned foods, although the incidence of botulism from wound infections has recently increased. Toxin type E is associated with preserved or fermented fish and marine mammals. These are the most important sources of botulism in Alaska, Japan, Russia, and Scandinavia.26

The botulinum toxin binds irreversibly to the presynaptic membrane of peripheral and cranial nerves and inhibits release of ACh at the peripheral nerve synapse. As new receptors are generated, patients improve.

**PRESENTING SIGNS AND SYMPTOMS**

**CLASSIC BOTULISM**

The disorder occurs at the NMJ, so neither sensory deficit nor pain occurs. Symptoms begin 6 to 48 hours after ingestion of the tainted food. The classic finding is a descending, symmetric paralysis. The nerves and muscles often affected first are the cranial nerves and bulbar muscles, which result in diplopia, dysarthria, dysphagia, and blurry vision. The deep tendon reflexes are normal or diminished. Signs and symptoms consistent with gastroenteritis may develop: nausea, vomiting, abdominal cramps, diarrhea, and constipation.

Because the toxins cause decreased cholinergic output, anticholinergic signs may be seen in the form of constipation, urinary retention, dry skin and eyes, and increased temperature. Pupils are often dilated and not reactive to light—an important point of differentiation from myasthenia gravis.

**INFANTILE BOTULISM**

Infantile botulism occurs as a result of the ingestion of *C. botulinum* spores that are able to germinate and produce toxin in the high pH of the gastrointestinal tract of infants (the same spores are not active in the gut of adults because of the lower pH). It occurs in infants between the age of 1 week and 11 months and has been implicated as a cause of sudden infant death syndrome. Clinical findings include constipation, poor feeding, lethargy, and weak cry; consequently, this diagnosis must be included in the differential diagnosis of a “floppy” infant.

**DIAGNOSTIC TESTING**

The diagnosis is based on clinical findings and exclusion of other processes. The toxin can be identified in both serum and stool, but the assay is not commonly available in most hospitals and thus requires a prolonged turnaround time. If the suspected food source is available, it should also be tested for the toxin.

**TREATMENT**

Treatment is initially focused on evaluating respiratory effort and securing the airway if respiratory compromise has occurred. The course of the disease can be shortened by administering botulinum antitoxin. A trivalent equine antitoxin is available from the Centers for Disease Control and Prevention, as well as from local poison control centers. Skin testing to assess for horse serum sensitivity should be carried out before administration.

**DIABETIC PERIPHERAL NEUROPATHY**

**EPIDEMIOLOGY**

A common complication of diabetes, diabetic peripheral neuropathy has a varied prevalence ranging from 34% to 60%, although higher rates often include asymptomatic neuropathies. It is a highly variable entity that is composed of several subsets. Of the various subsets of diabetic neuropathy, distal symmetric polyneuropathy is the most common, with up to 54% of patients with diabetic neuropathy having this variant. It is seen in patients with type 1 diabetes after 5 years and early in the course of type 2 diabetes.27,28

**PATHOPHYSIOLOGY**

Diabetic peripheral neuropathy encompasses any neuropathy in a diabetic patient not attributable to other causes. Although the most common form is distal symmetric polyneuropathy, diabetes also leads to focal and autonomic neuropathies. It is accompanied by significant morbidity: the most common cause of nontraumatic amputation is injury resulting from the impaired sensation associated with diabetic peripheral neuropathy that fails to heal because of the impaired blood flow in patients with diabetic vasculopathy.

Hyperglycemia affects the peripheral nerves by several proposed mechanisms:

1. Oxidative stress
2. Glycosylation of nerve proteins
3. Changes in the diabetic vasculature resulting in increased resistance and decreased flow to the peripheral nerves

Motor, sensory, and small and large fibers can all be involved. Diabetic peripheral neuropathy is an example of a distal axonopathy resulting in length-dependent “dying back” of the affected nerves. This dying-back phenomenon produces the typical stocking-and-glove distribution of diabetic neuropathy.29

**PRESENTING SIGNS AND SYMPTOMS**

Several neuropathic syndromes can be found in diabetic patients and are often present concurrently (Table 97.3). For example, patients may have a sensorimotor polyneuropathy with subsequent development of a mononeuropathy of the upper extremity.30

**TREATMENT**

Disease modification has the greatest effect on the progression of diabetic neuropathy; although the cause is multifactorial, a clear relationship between glycemic control and neuropathy exists. The Diabetes Control and Complications Trial showed...

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED PERIPHERAL NEUROPATHY

EPIDEMIOLOGY

Peripheral nervous system disease associated with HIV infection most commonly takes the form of a distal sensory polyneuropathy. The prevalence of symptomatic patients is 35%, although an additional 20% of asymptomatic patients have electrophysiologic evidence of disease.

PATHOPHYSIOLOGY

The distal peripheral neuropathy associated with HIV disease has two causes. There does not appear to be direct nervous...
invasion by HIV, although proteins produced by the virus may have associated neurotoxicity. The resultant inflammatory mediators, including macrophages and cytokines, probably play a role as well. Since the introduction of highly active antiretroviral therapy (HAART), a second proposed mechanism has implicated mitochondrial toxicity because of the medications themselves. Both causes primarily affect small unmyelinated fibers and may progress to involve larger myelinated fibers. The neuropathy demonstrates a dying-back axonal pattern with distal axonal degeneration.35

PRESENTING SIGNS AND SYMPTOMS

The initial signs and symptoms may be similar to those found with diabetic peripheral neuropathy, thus making it difficult to distinguish between them. Patients typically have the symptom of painful feet, usually without associated weakness. Physical examination will probably demonstrate decreased sensation distally, as well as diminished deep tendon reflexes.

DIAGNOSTIC TESTING

Before HIV-associated peripheral neuropathy is diagnosed, other causes such as diabetes, vitamin B12 deficiency, or other neurotoxic drugs must be ruled out. The history and physical examination largely drive the diagnosis of HIV-associated peripheral neuropathy. HAART-associated and non–HAART-associated neuropathy can be very difficult to distinguish clinically. Some patients with antiretroviral toxicity may have a more rapidly progressive course, at times temporally linked to the initiation of medication. The most effective diagnostic strategy is cessation of the suspected medication, which may result in improvement or resolution of the symptoms over a period of several weeks.

TREATMENT

The goals of treatment are similar to those for diabetic peripheral neuropathy: control of the primary disease process is important. Potential toxic drugs should be discontinued if appropriate. Painful neuropathy may be managed with NSAIDs, topical analgesics such as lidocaine patches, anticonvulsants, antidepressants, or narcotic analgesics.36 Randomized controlled trials have demonstrated the effectiveness of pain control over placebo along with the use of specific antiepileptics such as gabapentin and lamotrigine.35,37

Most patients with peripheral nerve disease can be treated on an outpatient basis. For patients with radiculopathy, compression mononeuropathy, or plexopathy, conservative treatment with analgesics and physical therapy is appropriate initially. This conservative treatment may take several weeks to reach maximal effect, which is important to convey to patients to improve compliance. Diabetics in particular may also benefit from referral to podiatry to prevent the complications of diabetic peripheral neuropathy. Patients with persistent symptoms despite a trial of conservative care may require referral for diagnostic testing with MRI or electrodiagnostics, pain management, or surgical evaluation.38 Patients with acute injury, such as fracture or dislocation, will require either immediate consultation by or follow-up with an orthopedist or hand specialist.

For patients with GBS, myasthenia gravis, LEMS, or botulism in whom respiratory compromise or aspiration is a concern, close monitoring as an inpatient is required, usually in an intensive care setting. If these patients are being discharged, the effect of changing or initiating pharmacologic therapy should be considered because a number of medications can exacerbate the underlying disease (notably aminoglycosides and immunosuppressants, including prednisone).

Demyelinating Disorders
Scott E. Rudkin

PATHOPHYSIOLOGY
The exact cause of demyelinating conditions is unknown, but an autoimmune or immune-mediated etiology is most likely. A molecular mimicry model postulates that an autoimmune attack on myelin is precipitated by an infectious organism that contains a protein similar to a myelin protein. The infection elicits an immune response by lymphocytes that recognize the cross-reactive protein; the activated lymphocytes then damage the myelin. The majority of the demyelinating disorders cause demyelination of the myelin sheath with relative sparing of the axon.

MS, transverse myelitis, and optic neuritis all affect the central nervous system. GBS, which primarily afflicts the peripheral nervous system, is now believed to cause both demyelination of the myelin sheath and axonal loss. Inflammatory lesions in peripheral nerve fibers cause focal demyelination with resultant slowing of conduction. Cranial nerves can also be affected.

PRESENTING SIGNS AND SYMPTOMS
In general, all the demyelinating disorders are characterized by an abrupt episode of loss of function. Depending on the area of the brain or nervous system affected, the patient may have sensory, motor, or autonomic symptoms.

MULTIPLE SCLEROSIS
In MS, the initial attack occurs abruptly (minutes to hours) from a single lesion. These attacks last between 6 and 8 weeks. Recovery between bouts of demyelination can be incomplete as in men and more frequently afflicts Caucasian patients, but all races can be affected. Onset of disease usually occurs in people between 20 and 50 years of age, with a peak occurring in those 30 years of age. The prevalence of MS varies widely with location; the highest prevalence is found at higher latitudes. This geographic variation suggests that MS may in part be caused by the action of some environmental factor.

GBS has an incidence of 3 per 100,000 individuals, which makes it the most common cause of flaccid paralysis. It has a slight male preponderance. The age at onset is bimodal, with the elderly and young adults most commonly being afflicted. There does not appear to be a geographic effect.

PERSPECTIVE
Second only to trauma, demyelinating diseases are a major cause of neurologic disability. Nerve conduction relies on the insulation that myelin provides the axon for transmission of impulses; demyelination disrupts this insulation, thereby resulting in abnormal signal propagation. This disruption results in sensory abnormalities, visual dysfunction, and muscle weakness.

Of the demyelinating conditions encountered by emergency physicians (EPs), multiple sclerosis (MS) is the most common. Other demyelinating conditions include optic neuritis, transverse myelitis, and acute inflammatory polyneuropathy (Guillain-Barré syndrome [GBS]).
or complete, depending on the amount of remyelination. Any part of the central nervous system can be affected. In decreasing order of frequency, the patient may exhibit optic neuritis, paresthesias in a limb, diplopia, trigeminal neuralgia, urinary retention, vertigo, or transverse myelitis. Depending on the spinal cord level, transverse myelitis can also cause loss of bladder or bowel function.

Ocular findings are the most common initial symptom. Optic neuritis is manifested as subacute monocular vision loss, although it can affect both eyes, and pain exacerbated with eye movement. It is the initial symptom in 25% and ultimately affects 50% of patients. The course usually progresses over a period of 2 weeks and may include headache, retroorbital or periorbital pain, and alterations in color vision and visual fields. Slit-lamp examination may demonstrate cell and flare in the anterior chamber. The optic disk is frequently swollen on initial evaluation. In addition to optic neuritis, the patient may have an afferent pupillary defect (Marcus Gunn pupil, or decreased pupillary constriction on direct light confrontation but a normal consensual response) or intranuclear ophthalmoplegia, which is characterized by dysconjugate gaze with limited adduction of one eye and nystagmus in the abducting eye on lateral gaze as a result of a lesion involving the medial longitudinal fasciculus.

Sensory symptoms in patients with MS usually include numbness, tingling, pins and needles sensation, and tightness and coldness of the limbs and trunk. Radicular pain and itching may also occur. Symptoms result from involvement of the spinothalamic, posterior column, and dorsal nerve roots. The loss of vibration sense is often most prominent. Ataxia is uncommon at the onset of MS, but it occurs to some degree in most patients. Exacerbation of sensory symptoms can occur frequently and in different patterns with a patchy distribution. Patients may note either paresthesias or loss of sensation.

Sensitivity to heat is a characteristic complaint. Exercise, fever, a hot bath, or other activities that raise body temperature may result in the appearance of new symptoms or the recurrence of old symptoms. These events occur as a result of a temperature-induced conduction block across partially demyelinated fibers. Symptoms resolve when body temperature returns to normal.

In addition to loss of sensation, patients may also report “positive” symptoms. In addition to causing a slowing of conduction, demyelination may result in ectopic impulses with resultant abnormal signal transmission and abnormal mechanical sensitivity. These aberrant signals can produce the Lhermitte sign—an electric-like tingling or vibrating sensation in the torso or extremities with neck flexion. The patient may also report flashes of light (phosphenes) and paroxysmal symptom, including trigeminal neuralgia, ataxia, and dysarthria or painful tetanic posturing of the limbs triggered by touch or movement.

Motor weakness may occur in any pattern, including paraparesis, hemiparesis, and monoparesis; the lower extremities are usually affected more than the upper ones. Upper motor neuron dysfunction accompanied by spasticity and increased reflexes may also be present. Transverse myelitis with ascending weakness and numbness below the level of the lesion can occur as an initial symptom.

Autonomic symptoms are a frequent finding. Patients have difficulty with bladder function, including frequency and urgency, and may experience urge incontinence from bladder spasticity or hesitancy, retention, and overflow incontinence from poor signal conduction. Constipation is the most common bowel complaint. This autonomic dysfunction is frequently very embarrassing and distressful.

Normal disease progression is variable: MS may remain indolent or occur in a progressive manner, with steady accumulation of neurologic deficits in the absence of clearly defined exacerbations. Typically, acute exacerbations are followed by partial or complete resolution. New neurologic deficits develop over the course of several hours or days, remain stable for a few days to a few weeks, and then gradually improve.

With repeated exacerbations, permanent neurologic deficits tend to develop. Patients usually have symptom-free intervals of months or years between attacks. Patients who initially have relapsing-remitting disease (two or more episodes lasting more than 24 hours separated by more than 1 month) and who then enter a progressive phase are said to have secondary progressive disease (initial exacerbations and remissions followed by slow progression over at least a period of 6 months), whereas those whose symptoms are progressive from the onset are said to have primary progressive disease (slow or stepwise progression over a period of at least 6 months). About 15% of patients have primary progressive disease; of those who initially have relapsing-remitting disease, 30% to 50% will experience progressive symptoms during the first 10 years.

**OPTIC NEURITIS**

Optic neuritis may occur by itself or be the initial symptom of MS. The relationship of optic neuritis to MS is controversial. Some regard optic neuritis as a distinct entity, but others consider it part of the clinical continuum of MS. More than half of all patients with MS have optic neuritis at some time during the disease. Patients with completely normal results on magnetic resonance imaging (MRI) and comprehensive cerebrospinal fluid (CSF) evaluation seldom progress to MS. Optic neuritis is usually manifested initially as unilateral vision loss and retrobulbar pain with eye movement.

**TRANSVERSE MYELITIS**

Like optic neuritis, transverse myelitis may occur in isolation or be part of the symptomatology of MS. It is usually manifested as paraparesis, which is initially flaccid and then spastic; as loss of sensation at a sensory level on the trunk; and as bowel and bladder dysfunction. Back pain precedes the neurologic symptoms, and the sensory symptoms may begin distally and ascend. The thoracic cord is most often affected.

**GUILLAIN-BARRÉ SYNDROME**

Patients with GBS have weakness, paresthesias, and decreased or absent deep tendon reflexes. The distribution typically includes distal involvement with symmetric paresthesias (pins and needles). It spreads proximally, with weakness occurring a few days later; weakness also progresses to involve the upper extremities. Weakness is most prominent in the lower extremities and tends to involve the proximal muscles. It is usually first manifested as difficulty rising from a chair. The disease progresses from a few days to 3 to 4 weeks (progressive phase), followed by a plateau phase (days to weeks) and then by a recovery phase lasting from weeks to months. Weakness is varied but can be profound and involve the face and
respiratory muscles. A loss or decrease in deep tendon reflexes is frequently the initial finding, and these reflexes should be tested if GBS is suspected. Variants include the acute axonal form, which has a poor prognosis, and the Miller-Fisher syndrome, which is characterized by ataxia, ophthalmoplegia, and areflexia.

**Differential Diagnosis and Medical Decision Making**

The differential diagnosis of demyelinating diseases includes conditions that cause progressive weakness. In due course the diagnosis of a demyelinating disorder becomes clear because few disorders relapse and remit over time. The role of the EP is to exclude other diseases that need immediate treatment.

Clinical factors that suggest a diagnosis other than MS (Table 98.1) include normal findings on neurologic examination, aphasia, predominance of pain, abrupt hemiparesis, quick (seconds or minutes) resolution of symptoms, and age younger than 10 or older than 50 years.

The diagnosis is usually made from the clinical signs and symptoms; MRI and other laboratory tests play a supporting role. Diagnosis requires evidence of dissemination of lesions in time and space and careful exclusion of other causes. The patient should have had more than one episode of neurologic dysfunction and evidence of white matter lesions in more than one part of the central nervous system or a change in a previous lesion. Although it is possible for a neurologist to diagnoses MS during an initial attack, provided that two clinical lesions are present and with corroborating laboratory testing, it is prudent for the EP to use a more conservative approach that requires two distinct attacks.

The EP should consider the diagnosis in a young adult with a history of two or more clinically distinct episodes of central nervous system dysfunction or the presence of highly suggestive symptoms (optic neuritis or intranuclear ophthalmoplegia). In 2005, the McDonald criteria revised the 2001 guidelines of the International Panel on MS to incorporate specific MRI findings and reaffirm the need for separation of clinical events and lesions in space and time. Diagnostic confidence is based on whether the criteria are fully met (diagnosis of MS), partially met (possible MS), or not met (not MS).

Table 98.2 lists characteristic factors differentiating demyelinating disorders.

Differential diagnoses for optic neuritis include anterior ischemic optic neuropathy, which is usually painless and found in patients older than 50 years; hereditary diseases such as Leber hereditary optic neuropathy; and toxic or nutritional optic neuropathies.

Transverse myelitis may superficially resemble GBS, but its asymmetric involvement, definite sensory level, lack of upper extremity involvement, urinary incontinence symptoms, and CSF pleocytosis make the diagnosis of GBS less likely. The differential diagnosis includes other causes of acute myelopathy such as compression of the cord by an extradural structural lesion, spinal cord neoplasms, ischemia, and systemic lupus erythematosus.

Heavy metal poisoning can also mimic GBS, but it is usually preceded by a gastrointestinal phase with vomiting and diarrhea. As discussed previously, transverse myelitis can superficially resemble this syndrome.

**Cerebrospinal Fluid Analysis**

With MS, CSF analysis (with electrophoresis) frequently demonstrates albuminocytologic dissociation with increased protein (usually less than 100 mg/dL) and a normal cell count.
However, 10% of patients have a normal CSF protein level. Mild mononuclear cell pleocytosis can be found during acute MS relapses, but total cell counts greater than 50/mm$^3$ are uncommon. During acute attacks of MS, especially those involving the spinal cord and brainstem, CSF may contain measurable amounts of myelin basic protein. Oligoclonal bands or abnormal immunoglobulin synthesis is found in about 90% of patients with a diagnosis of MS. Though not specific to MS, these findings support the diagnosis of MS in equivocal cases.

CSF studies may demonstrate elevated protein levels and leukocytes in patients with transverse myelitis; such studies are not generally required for optic neuritis but are usually obtained to help in the diagnosis of MS.

### NERVE CONDUCTION STUDIES

Electrodiagnostic testing may demonstrate conduction blocks, differential slowing, or focal slowing. Slowing of conduction over demyelinated segments of axons or over incompletely remyelinated pathways provides a useful marker for identifying additional subclinical lesions in the sensory pathways. Conduction can be measured along the visual, auditory, and somatosensory pathways with the use of summated cortical evoked responses. In these tests, a time-locked recording of...
supports the use of oral methylprednisolone (500 mg daily for 5 days with a 10-day tapering period).6

In patients with relapsing-remitting MS, disease-modulating drugs reduce the frequency of attacks, the rate of increase in lesions seen on MRI, and the accumulation of disability. In patients with relapsing disease of mild to moderate severity, interferon beta-1b, given subcutaneously every other day, reduced the year-on-year relapse rate by one third and severe attacks by one half. The effect was maintained for up to 5 years.5,6 In another study, interferon β1b reduced MRI contrast-enhanced lesions by 1.6%, as opposed to a 15% increase in those receiving placebo. The number of enlarging or new lesions was also significantly reduced.7 Antibodies developed in 35% of patients taking interferon β1b, but there is a lack of consistent effect of antibodies on clinical outcome. Additionally, these antibody levels were found to have disappeared in the majority of patients after 8 years of treatment.8,9

Interferon β1a produced similar benefits when given intramuscularly three times per week, with a 17% reduction in the relapse rate. When compared with weekly, low-dose interferon β1a, high-dose interferon β1a given three times per week demonstrated a 32% relative reduction in steroid use to treat relapses.10

Glatiramer, a synthetic random compound composed of four amino acids, is found in myelin. Its exact mechanism is unknown, but it is believed that glatiramer acetate binds to the major histocompatibility complex class II antigen and induces organ-specific T helper type 2 cell responses, thus converting proinflammatory T cells to antiinflammatory agents.11 Treatment with glatiramer reduces the relapse rate by 30% and may delay disease progression.12

Natalizumab, a monoclonal antibody against α4 integrins, is effective for relapsing-remitting MS. The reduction in annualized relapse rates with natalizumab is similar to that with glatiramer or interferon β.13 However, it is not a first-line agent because it can cause progressive multifocal leukoencephalopathy in 0.1% of cases.14

Mitoxantrone is an anthracenedione, antineoplastic agent approved for the relapsing-remitting and progressive forms of MS. Cardiotoxicity, acute leukemia, and questionable efficacy limit it to treatment failures or cases of rapidly progressive MS.

Fingolimod, the first oral treatment option for MS approved by the Food and Drug Administration, is a sphingosine analogue that blocks lymphocyte release from lymph nodes through interaction with the sphingosine 1-phosphate receptor. Fingolimod can significantly reduce relapse rates when compared with interferon β1a. However, fingolimod is associated with life-threatening infections, bradycardia, atrioventricular block, tumor development, and macular edema.15

Specific therapies for relief of symptoms are provided in Table 98.3.

TRANSVERSE MYELITIS

Corticosteroids and plasma exchange may be beneficial in the treatment of transverse myelitis.16 In a small case series, patients treated with steroids were able to walk after a median time of 23 days versus 97 days for historical controls.17 Plasma exchange is often used for those with more severe disease (e.g., unable to walk) who fail to improve with IV steroid therapy.18 The prognosis for transverse myelitis is variable.
Demyelinating Disorders

OPTIC NEURITIS

IV methylprednisolone (1 g/day for 3 days) followed by oral prednisone (1 mg/kg/day for 11 days with a 4-day taper) and interferon β1a (30 mcg intramuscularly once a week) for patients at high risk for MS based on MRI has been shown to hasten recovery of vision in patients with optic neuritis.24 However, this therapy shows little residual benefit at 1 year. Additionally, oral prednisone therapy alone was found to actually increase the recurrence rate.20 Regardless of therapy, most patients recover their vision within a month.

GUILLAIN-BARRÉ SYNDROME

Therapy is largely supportive. Most patients recover function if they survive the acute phase. The key therapeutic measure is ventilatory support. FVC should be measured in all patients in whom GBS is suspected. Patients with an FVC of less than 20 mL/kg should be admitted to the intensive care unit because of their high risk for ventilatory insufficiency. For those with FVC lower than 15 mL/kg, intubation is indicated. If intubation is necessary, succinylcholine should be avoided because it can cause hyperkalemia with resultant arrhythmia and hypotension. Dysautonomia can result in severe paroxysmal hypertension, orthostatic hypotension, and arrhythmias. Cardiovascular function should be monitored carefully. Plasmapheresis and IV gamma globulin therapy have both been shown to reduce recovery time by 50%. IV gamma globulin is less expensive and easier to administer, but the risk for viral transmission is greater. IV steroids are frequently administered, but their actual benefit is questionable.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

All patients with a first episode of a demyelination disorder merit neurology consultation. Although outpatient therapy is possible for a subset of these patients, this decision is best left to the neurologist. As discussed previously, the typical course of MS is a relapsing-remitting pattern. During an acute exacerbation, the patient is frequently admitted for IV steroid therapy, but oral treatment is possible.

Hospital admission is required for GBS, and FVC measurement typically guides selection of the appropriate level of care. The majority of patients are hospitalized for a month or

The National Multiple Sclerosis Society (http://www.nmss.org), Guillain-Barré Foundation (http://www.gbsfi.com/), and Transverse Myelitis Foundation (http://www.myelitis.org/) provide excellent patient resources and offer support groups for both patients and family. Patients are at risk for exacerbation of symptoms and progression of disease from an elevated core temperature. Aggressive fever control and determination of its cause are important.

There is no cure for demyelinating disorders, but current therapies can reduce their frequency and severity. Patients with optic neuritis have a worse prognosis with oral steroid therapy. If steroids are used, they must be given intravenously.

Patients with symptoms of progressive weakness and sensory symptoms must be assessed rapidly for Guillain-Barré syndrome. With aggressive therapy, respiratory failure can be avoided.
longer, and with careful attention to respiratory function, morta-
ality is now less than 5%.

Patients should undergo ophthalmology and neurology evaluation for manifestations of optic neuritis. If steroid therapy is needed, hospital admission is necessary because steroids may worsen the clinical outcome.

Seizures
Asim F. Tarabar, Andrew S. Ulrich, and Gail D’Onofrio

KEY POINTS

- Seizures are classified by the clinical finding of abnormal electrical impulses within the cerebral cortex.
- Direct morbidity and mortality are the result of inadequate cerebral perfusion of oxygen and glucose to the brain, as well as secondary trauma.
- Serum glucose levels should be checked in all seizure patients immediately.
- Emergency department treatment is directed at urgent cessation of seizures, prevention of further activity, and diagnosis and correction of the underlying cause.
- Intravenous benzodiazepines are the initial treatment of most seizures.
- Isoniazid can cause intractable seizures with an overdose; the antidote is pyridoxine.
- Eclamptic seizures, most common in the third trimester, can also occur postpartum; the antidote is intravenous magnesium sulfate.
- One third of eclamptic woman do not have the classic triad of hypertension, proteinuria, and edema.
- Most chronic seizure patients can be discharged home safely after emergency department evaluation and correction of anticonvulsant levels if needed.
- Patients with seizure disorders should have adequate control and close follow-up with a neurologist before driving vehicles or operating machinery.

EPIDEMIOLOGY

Seizures are a common complaint of patients seeking care in emergency departments (EDs). By some estimates, seizures account for 1% to 2% of all ED visits. Epilepsy, a condition resulting in recurrent, unprovoked seizures, affects upward of 4 million people; however, as much as 10% of the population will have at least one seizure during their lifetime.

The natural history of untreated epilepsy is essentially unknown. Based on retrospective data, it was found that 32% of patients with a first epileptic seizure will experience a second attack within 1 month, 51% within 3 months, and 87% within the first year. Some strong predictors for recurrence of seizures include a history of previous neurologic insult, abnormal findings on neurologic examination, or an electroencephalogram (EEG) with epileptiform abnormalities and circadian timing. Approximately 50% patients in whom epilepsy is diagnosed will become seizure free with only single-drug treatment. The addition of a second or third drug will control another 20%, and intractable seizures that are poorly responsive to standard medical treatment will develop in about 30%.

PATHOPHYSIOLOGY

Seizures are the result of inappropriate electrical activity in the brain, whereas syncope is caused primarily by transient hypoperfusion within the brain. Uncontrollable electrical discharges can originate from a single area as a result of an underlying structural condition (e.g., tumor, scar, bleeding), or it can be caused by an imbalance in inhibitory (γ-aminobutyric acid [GABA]) and excitatory (N-methyl-D-aspartate) receptor activities. The latter is usually due to toxic or metabolic causes.

The specific seizure activity is determined by the area in the brain involved (Box 99.1). Some of these abnormal electrical discharges may remain localized, whereas others may involve larger areas of the brain. Subsequently, the resultant clinical spectrum includes isolated focal motor activity, as well as generalized motor and sensory abnormalities, including altered mental status and behavioral changes.

PRESENTING SIGNS AND SYMPTOMS

If available, the previous medical history may reveal risk factors (Box 99.2) associated with the development of seizures. The history can be obtained from the patient (after normalization of mental status), family, primary care physicians, old medical records, or emergency medical service (EMS) personnel.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The most common serious condition that can be misinterpreted as a seizure is syncope. There may be important
clinical signs or preceding events that can help differentiate these two entities (Table 99.1). In many circumstances patients will be unable to provide critical information, so it is important to try to obtain an accurate description from anyone who witnessed the event (e.g., family, coworkers, EMS personnel). Aside from syncope, several other medical conditions need to be included in the differential diagnosis of seizures (Boxes 99.3 and 99-4; Table 99.2).

Though rare, various disturbances in electrolytes may precipitate seizures, including hyponatremia, uremia, and hypocalcemia. A serum electrolyte assay is recommended for patients with new-onset seizures. Between 2.4% and 8% of patients with seizures will have electrolyte abnormalities. Despite the fact that the majority of these abnormalities will be clinically insignificant, they should be evaluated and can often be easily corrected in the ED.

If an overdose is suspected, both blood and urine toxicologic screens should be performed.

Measuring the serum prolactin level has no clinical utility in the ED because the results cannot be obtained in a timely manner. However, it may be useful for the consulting service that will conduct further work-up to help differentiate between epileptic (generalized tonic-clonic or complex partial seizures) and psychogenic nonepileptic seizures. It should be performed within 10 to 20 minutes after a suspected event.

Prolactin levels of at least twice baseline are considered abnormal (positive). Prudent clinicians may decide to have prolactin levels measured, especially in patients with the symptoms suggestive of nonepileptic or psychogenic seizures. 

An electrocardiogram (ECG) should be obtained in every patient with a first onset of seizures or with suspicion of a

**BOX 99.1 Seizure Classification**

**Partial (Focal) Seizures (One Area or Brain Hemisphere Involved)**
- Simple (awareness retained)
- Motor
- Somatosensory
- Autonomic
- Psychogenic
- Complex (altered awareness and behavior)

**Secondary Generalized Seizures (Spreading from One Area to the Whole Brain)**
- Generalized Seizures (Seizures Involving the Whole Brain with Alteration of Consciousness)
  - Tonic-clonic
  - Grand mal, convulsions
  - Positive loss of consciousness, stiffening of the body with the jerking movements of the limbs

**Secondary Seizures**
- Toxin induced
- Substance withdrawal
- Metabolic

**Absence**
- Petit mal: staring fit or trancelike state
- Tonic or atonic
  - Drop attack: abrupt fall, either with stiffening (tonic) or with loss of muscle tone (atonic)
- Myoclonic
  - Sudden muscle jerks

**BOX 99.2 Differential Diagnosis of Conditions Resulting in Seizurelike Symptoms**

- Breath-holding spells
- Episodic dyscontrol syndrome, rage attacks
- Fugue states
- Heat stroke, exhaustion
- Hyperventilation
- Migraine narcolepsy, cataplexy
- Movement disorders
- Night terrors
- Nonepileptic seizures
- Panic attacks
- Paroxysmal vertigo
- Psychogenic seizures
- Syncope
- Transient global amnesia
- Transient ischemic attack, stroke (ischemic, hemorrhagic)
Factors Precipitating Seizures

Flashing lights (strobe light, Pokémon seizures)
Menstrual period (catamenial seizures)
Recent head trauma
Metabolic
- Hypoglycemia, hyperglycemia
- Hypomagnesemia
- Hyponatremia, hypernatremia
New medications (interfering with the metabolism of anticonvulsants)
Sleep deprivation
Toxins, drugs of abuse
- Alcohol use, withdrawal
- Baclofen pump malfunction; overdose, withdrawal
- Cocaine, sympathomimetics
Medication noncompliance
- Lack of insurance, unable to refill medications
- Substance abuse
- Change in dose or generic versus brand medications

Differential Diagnoses of Secondary Seizures

Central nervous system infections (encephalitis, meningitis)
Eclampsia
Metabolic
- Hypoglycemia
- Hyponatremia
- Hypothyroidism
- Hyperammonemia
Trauma (subarachnoid hemorrhage)
Toxic
- Anticholinergics
- Baclofen overdose, withdrawal
- Cyclic antidepressants
- Carbon monoxide
- Isoniazid
- Sedative-hypnotic drug withdrawal

Toxic cause of decreased central nervous system (CNS) perfusion. In addition to ischemia, the most important disorders that have to be excluded are related to conduction abnormalities and consequent dysrhythmias. ECGs are used to evaluate widening of the QRS complex because of sodium channel blockade after an overdose of certain medications, particularly cyclic antidepressants. More specific changes on the ECG, such as a terminal 400-msec R wave in the aVR lead, can also assist in identifying toxicity from cyclic antidepressants. A prolonged QTc interval can be found with overdose of citalopram (a selective serotonin reuptake inhibitor with proconvulsive properties). Tachyarrhythmias are often seen in the setting of cocaine and methylxanthine toxicity (theophylline, caffeine) (Box 99.5).

Patients at high risk for meningitis or encephalitis should be treated with ceftriaxone (2 g intravenously [IV]), vancomycin (1 g IV), and acyclovir (500 mg IV), even before the results of a spinal tap are available. In addition, patients should be placed in an isolation room with droplet precautions.

Neurocysticercosis (NCC) is the most common parasitic CNS infection in the world and has been increasing in the United States since 1980. In endemic areas (Latin America, Asia, Africa), NCC is considered to be main cause of late-onset epilepsy, and seizures are reported to be the most
common symptom and occur in 70% to 90% of patients. The majority of patients will respond to treatment with phenytoin or carbamazepine.

Albendazole is the mainstay antiparasitic drug for the treatment of NCC (15 mg/kg/day divided into two doses twice daily for 8 to 30 days). Patients in whom NCC is diagnosed may require treatment with steroids to control the inflammation and treat meningitis, cysticercal encephalitis, and angiitis. Treatment is usually started with dexamethasone (4 to 12 mg/day), and it can be replaced with prednisone (1 mg/kg/day) for long-term treatment.

Computed tomography (CT) of the brain should be performed in every patient with a first onset of seizures and in those with persistent change in mental status, focal neurologic deficit, or suspicion of an organic intracerebral lesion. Early CT scanning is essential for identifying surgically correctable causes. If there is a concern that trauma occurred, CT can be used to rule out cervical spine and intracerebral injury (Box 99.6).

Magnetic resonance imaging (MRI) is more sensitive than CT and can be effective in diagnosing additional lesions; namely, temporal sclerosis, cortical dysplasia, vascular malformations (e.g., arteriovenous aneurysms), and some tumors. Its use will depend on availability and time constraints, but MRI is not typically done on an emergency basis. The majority of patients will be able to undergo MRI as an outpatient.

The EEG records brain electrical activity and is used for definitive diagnosis of epilepsy and related conditions. The need for EEG in the emergency setting is limited, usually to patients whose seizure activity is uncontrollable despite aggressive treatment or to patients whose seizure activity is more difficult to diagnose.

Intubated patients who are paralyzed or have undergone induction of phenobarbital coma and general anesthesia should be monitored continuously with an EEG to exclude seizure activity because in these situations obvious seizure activity may not be apparent as a result of neuromuscular paralysis. Another indication may be patients who have unexplained altered consciousness that can be due to persistent non–tonic-clonic seizure activity.

If patient is transported by EMS, multiple steps in the treatment (Fig. 99.1) protocol can be initiated and completed by...
Most seizures will stop spontaneously or soon after the initiation of appropriate treatment. One of the primary goals during the evaluation and treatment of patients with seizures is to preserve a patent airway and oxygenation, as well as prevent aspiration in patients who are in the postictal phase. Despite very dramatic signs and symptoms, including cyanosis, very few patients who are actively experiencing seizures will require endotracheal intubation.

EMS personnel, including administration of anticonvulsants, airway protection, correction of glucose, and elicitation of the initial history, including drug exposure. It is essential that an attempt be made to control seizure activity immediately on arrival at the ED, so discussion of treatment will occur simultaneously with discussion of the diagnostic approach. Maintenance of adequate cerebral perfusion and consequent oxygen and glucose supply to the brain is the goal of treatment.

Fig. 99.1 Steps in treatment. *abx,* Antibiotics; *AIDS,* acquired immunodeficiency syndrome; *CBC,* complete blood count; *C-spine,* cervical spine; *CT,* computed tomography; *ECG,* electrocardiogram; *EEG,* electroencephalogram; *β-HCG,* β-human chorionic gonadotropin; *HIV,* human immunodeficiency virus; *Hx,* history; *IV,* intravenous; *LP,* lumbar puncture; *MRA,* magnetic resonance angiography; *MRI,* magnetic resonance imaging; *r/o,* rule out.
Cessation of motor seizure activity as a result of chemical paralysis does not indicate cessation of neuronal seizure activity. It is essential that clinicians continue to closely monitor for seizures in intubated patients, including, eventually, EEG monitoring. While awaiting placement of the EEG electrodes, clinicians should use the pupillary reflex as an indicator of seizure activity. In a paralyzed patient, the pupillary light reflex remains intact. Lack of a pupillary light reflex should suggest ongoing seizure activity.

A rapid bedside or field fingerstick test should be performed immediately to evaluate for low serum glucose. One ampule of 50% dextrose is administered IV to a hypoglycemic patient. It should be repeated if the patient remains hypoglycemic. Glucagon, 1 mg intramuscularly (IM) or subcutaneously, should be given to hypoglycemic patients without intravenous access as a temporizing measure. Glucagon, however, can cause vomiting, thus increasing the risk for aspiration in an unresponsive or seizing patient.

Benzodiazepines should be administered immediately because they have been shown to control the majority of seizures regardless of cause through an increase in GABA activity. Studies have shown that lorazepam (Ativan, 0.05 to 0.1 mg/kg up to a maximum of a 4-mg initial dose) is more effective than diazepam (Valium, 5 to 15 mg IV) for the initial control of seizures, although both agents are acceptable. If intravenous access is difficult, intramuscular or rectal administration of valium (Diastat, rectal form of valium, 0.2 mg/kg up to 20 mg PR) or lorazepam (0.1 to 0.2 mg/kg IM) is an alternative. Intranasal midazolam (Versed) has also been used. Continued seizure activity should be treated with a second dose of a benzodiazepine, along with the addition of a second agent (e.g., barbiturate, propofol, pyridoxine/vitamin B6) and attention to disorders inciting the seizure (e.g., increased intracranial pressure, CNS infection, eclampsia, drug-related seizures) (Table 99.3).

Phenytoin (Dilantin) is a second drug of choice but requires patient monitoring when administered IV. A loading dose of 15 to 20 mg/kg should be started simultaneously with the

**SECTION IX • NERVOUS SYSTEM DISORDERS**

**Table 106.**
administration of benzodiazepines. This should be done for patients with elevated intracranial pressure (e.g., tumor, bleeding, hydrocephalus), as well as for those who are not compliant with the phenytoin prescribed. Phenytoin has poor water solubility and has to be formulated with propylene glycol, so intravenous delivery is rate-limited (no faster than 50 mg/min) to prevent hypotension.

If the emergency physician suspects drug-induced seizures, including withdrawal (alcohol, sedative-hypnotics, baclofen), phenytoin should not be used as a second drug of choice because it has disadvantageous properties (negative inotropic and proarrrhythmogenic properties). For drug-related seizures resistant to benzodiazepines, barbiturates, propofol, and pyridoxine should be considered.

Fosphenytoin (Cerebyx) is less irritating to veins, less toxic to tissues, and less likely to induce dysrhythmias and can be administered either IV or IM, but it is more expensive. Fosphenytoin is a prodrug of phenytoin. Plasma phosphatase enzymes cleave phenytoin from fosphenytoin, which takes 8 to 15 minutes when administered IV. With intramuscular dosing, approximately 30 minutes is needed for therapeutic levels to be achieved. The loading dose is 15 to 20 mg/kg (phenytoin equivalent) IV or IM. Fosphenytoin is water soluble and associated with far less tissue toxicity at the infusion site; however, it is just as cardiotoxic as phenytoin. Fosphenytoin is typically reserved for short-term parental administration.

Barbiturates are potent respiratory depressants, much more so than benzodiazepines, so clinicians should be concerned about the potential for intubation. Traditionally, phenobarbital (10 to 20 mg/kg IV administered at a rate of 25 to 50 mg/min) has been used as a drug of choice, but because of rate-limited administration, pentobarbital (100 mg IV administered at a rate of 25 mg/min), a shorter-acting barbiturate, should be considered for resistant seizures.

Patients whose seizure activity has ceased before arrival at the ED might be candidates for oral loading of antiepileptic medications. The oral loading regimen for patients who have no detectable serum level of phenytoin (Dilantin) is 20 mg/kg in divided doses administered over a day, with a maximum dose of 400 mg every 2 hours. A suspension formulation is preferred over tablets because of better absorption and higher serum levels. Adverse reactions to phenytoin, such as ataxia, somnolence, and confusion, are decreased with a slower loading rate.

The usual typical outpatient oral dose is 100 mg three times per day. Because the half-life of phenytoin is about 24 hours, some patients take 300 mg once a day. The therapeutic serum level is 10 to 20 mg/L. Even at this level, some patients will experience mild sedation and cognitive effects. With long-term use, gum and skin thickening can occur and may not be reversible. One in 10,000 will experience Steven-Johnson syndrome. Phenytoin can cause folate deficiency, which leads to anemia and bone problems, so daily use of multivitamins is recommended.

Patients with chronic seizures who have a typical event may require only evaluation of the antiepileptic level and triggering factors. However, new organic pathology that may lower the seizure threshold (e.g., infection, electrolyte abnormality, trauma) should be excluded. Any precipitating factors that may unmask a chronic seizure disorder or explain an increase in seizure reoccurrence in patients with therapeutic levels of anticonvulsants should be identified (see Box 99.4). In the absence of concomitant pathology, the majority of patients with chronic seizures can be discharged home if they return to baseline.

In addition to the classic or traditional anticonvulsants (phenytoin, carbamazepine, phenobarbital), the emergency physician may encounter many new anticonvulsants. The majority of new drugs do not have timely measurable serum levels.

Patients who are undergoing chronic anticonvulsant treatment should receive an additional oral dose before discharge if the level is found to be subtherapeutic. It is also reasonable to give a dose of one of the newer anticonvulsants in the ED to patients who are noncompliant with treatment (Table 99.4).

Neurology consultation should be considered for patients in status epilepticus (SE) or for breakthrough seizures. Trauma and neurosurgery consultation should be obtained for patients with intracranial bleeding and complex trauma. Finally, an infectious disease consultation could be considered for some patients with infectious pathology and acquired immunodeficiency syndrome (AIDS).

**SPECIAL CIRCUMSTANCES**

**STATUS EPILEPTICUS**

SE is defined as continuous seizure activity in excess of 5 minutes or consequent seizure activity without return to consciousness. Diagnostic assessment of patients in SE should be performed in parallel with treatment, and most of the time the diagnosis can be based on clinical findings.

Early aggressive administration of intravenous anticonvulsants is the keystone for successful treatment of SE. Benzodiazepines and barbiturates will control seizure activity through the increased action of GABA. With longer durations of SE, there may be loss of responsiveness to GABAAergic medications because of a theoretically time-dependent loss of synaptic GABA_A receptors.

For patients who fail to respond to first-line anticonvulsant therapy, especially if exposure to isoniazid (INH) is suspected because of tuberculosis, 5 g of vitamin B6 should be administered IV.

**PREGNANCY**

Pregnancy can precipitate seizure episodes in patients with underlying seizure disorders. Women with epilepsy can also experience seizures during and after abortions. Sometimes during cervical dilation, woman can experience cervical shock, which is a type of vasovagal syncope resulting in bradycardia, relative CNS hypoperfusion, and occasional tonic-clonic activity that is much shorter in duration and lacks any postictal phase.

The incidence of eclampsia in the western world ranges from 1 in 2000 to 3000 pregnancies. The incidence of seizures in woman with preeclampsia is approximately 1 in 300. Eclamptic seizures can occur from the 20th week of gestation up to 7 days after delivery. Seizures up to 26 days after delivery have been reported. During this period every new-onset seizure should initially be treated as eclamptic until proved otherwise. Clinician should be aware that up to 30% of eclamptic woman do not necessarily have the “classic symptoms”—hypertension, proteinuria, and
edema. Other than early detection of preeclampsia, no tests are reliable in predicting the development of eclampsia. All female patients of childbearing age who are seen following seizure activity should be tested for pregnancy. Pregnant women who have hypertension, proteinuria, headache, visual disturbances, abdominal pain with nausea, or edema should be presumed to have eclampsia until proved otherwise. The cerebral abnormalities with eclampsia (mostly vasogenic edema) are similar to those found with hypertensive encephalopathy.

The treatment of choice is magnesium and concomitant delivery of the fetus. Magnesium sulfate is administered at a dose of 4 to 6 g IV over a 15-minute period, followed by a maintenance infusion of 2 g/hr. Magnesium sulfate is not an anticonvulsant, and its mechanism of activity remains unclear. After administration, deep tendon reflexes should be monitored closely because hyporeflexia will precede respiratory insufficiency, a complication of hypermagnesemia. Hydralazine is usually indicated in conjunction to manage blood pressure. Benzodiazepines and phenytoin, though not typically first-line agents for the treatment of eclamptic seizures, may also have some short-term benefit.

**HUMAN IMMUNODEFICIENCY VIRUS**

People infected with human immunodeficiency virus (HIV) may have a CNS mass or infection as a cause of the seizure. This can be the first manifestation of AIDS. HIV-positive patients who have a seizure require a CT scan and, if negative, a lumbar puncture. HIV encephalopathy or meningitis must be considered (Box 99.7).

**CENTRAL NERVOUS SYSTEM PATHOLOGY**

Patients with underlying intracranial hemorrhage who are taking anticoagulants or have an elevated international normalized ratio may require the administration of fresh frozen plasma and vitamin K to prevent further bleeding. Patients with brain tumors, evidence of increased intracranial pressure, or hydrocephalus require immediate neurosurgical consultation.

- Human immunodeficiency virus–associated encephalopathy, acquired immunodeficiency syndrome–dementia complex
- Progressive multifocal leukoencephalopathy
- Central nervous system tuberculosis
- Neosyphilis
**DRUG- AND TOXIN-INDUCED SEIZURES**

Any drug that decreases GABA activity in the CNS can cause seizures. Drug-related seizures are a result of either over-stimulation (glutamate) or lack of inhibition (GABA withdrawal) of electrical brain activity. Treatment is generally directed at increasing GABA activity with benzodiazepines. However, certain drugs are associated with particular types of toxicities that may require specific treatments or antidotes (Tables 99.5 and 99.6).

Removal of the toxin or drug plus secondary decontamination is the hallmark of treatment of drug- and toxin-induced seizures.

**Cocaine**

The most commonly abused substance that causes seizures is cocaine. Benzodiazepines will help control seizures, agitation, and hyperthermia. In patients with prolonged seizures, focal neurologic findings, or persistent changes in mental status, CT of the brain should be used to exclude intracerebral bleeding. Fluid resuscitation is important to protect against renal damage from potential rhabdomyolysis. If the patient is hyperthermic, cooling measures with intravenous fluids, ice packs, and even ice baths for refractory hyperthermia should be applied to avoid multiorgan failure and death.

**Alcohol**

Alcohol-related seizures (ARSs) are defined as adult-onset seizures, generally after the age of 25, that occur in the setting of chronic alcohol dependence or withdrawal. Preexisting epilepsy, structural brain lesions, use of illicit drugs, or other metabolic disorders can also increase the frequency of seizures in patients who drink heavily. They are typically brief, generalized tonic-clonic seizures that occur 6 to 48 hours after the last drink. Without treatment, 60% of patients will experience multiple seizures over a period of approximately 6 hours.

The diagnosis of ARSs is made only after exclusion of other potential causes. New-onset seizures in an alcohol-dependent patient should prompt a thorough evaluation similar to that described for any person with a new-onset seizure.

In majority of the patients, lorazepam (Ativan), 2 mg IV, has been shown to prevent subsequent seizures after the first one. In a randomized controlled trial of patients with ARSs, only 3% had a subsequent seizure after the first one. In a randomized controlled trial of patients with ARSs, only 3% had a subsequent seizure during a 6-hour observation period as compared with 24% in the placebo group ($P < .001$).

All patients should be offered referral to a specialized alcohol treatment facility (when possible) where they can be treated with longer-acting benzodiazepines. If patients are unwilling to be referred, they should be observed for at least 3 hours.

**Opioids**

Despite the fact that opioids are not generally associated with the seizures, it is worth mentioning several exceptions, including meperidine (Demerol), propoxyphene (Darvon), and tramadol (Ultram). Administration of naloxone can actually precipitate and worsen meperidine-associated seizures.

**MDMA:** 3,4-Methylenedioxymethamphetamine (“Ecstasy”)

MDMA is an amphetamine-related drug that is associated with seizure activity. Typically, patients who are ingesting MDMA during “rave parties” experience brief tonic-clonic seizures as a result of hyponatremia. MDMA can cause a transient syndrome of inappropriate antidiuretic hormone secretion, in addition to the dilutional hyponatremia secondary to excessive free water consumption. Most patients can be treated by fluid restriction and observation.

**OTHER MEDICATIONS TYPICALLY ASSOCIATED WITH SEIZURES** (Table 99.7)

**Cyclic Antidepressants**

Cyclic antidepressants are notorious for their propensity to cause seizures as a result of GABA inhibition. Seizures are typically a manifestation of severe toxicity, so airway protection, complete gastrointestinal decontamination (charcoal, lavage if indicated), and intravenous benzodiazepines should be initiated immediately. Sodium bicarbonate, a primary treatment of cyclic antidepressant overdose, is effective in treating cardiac conduction abnormalities but does not affect seizure activity.

**Isoniazid**

The typical manifestation of INH-induced seizures is SE that does not respond to conventional treatment with GABAergic drugs or phenytoin. INH prevents GABA synthesis, and the treatment is vitamin $B_6$ (pyridoxine). If the dose of ingested INH is known, the antidote treatment is 1 g of vitamin $B_6$ for each gram of INH. However, if the dose is not known, empiric administration of 5 g is recommended. Pyridoxine should be diluted to a concentration of 50 mL/g and administered IV over a period of 5 to 10 minutes. The dose should be repeated if seizures continue or if the patient remains lethargic.

**Methylxanthines (Caffeine, Theophylline)**

Overdoses of caffeine and theophylline are notorious for causing seizures through the antagonism of adenosine, an inhibitory neurotransmitter. Usually, the seizures are short acting and can be controlled with benzodiazepines. However, in severely toxic patients, hemodialysis may be necessary.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Every patient with persistent seizures, change in mental status, or underlying medical condition that requires hospital treatment (e.g., sepsis, overdose, trauma) should be admitted. Patients in SE should be admitted to an intensive care setting (Box 99.8).

**DOCUMENTATION**

Subtherapeutic levels should be documented in addition to the planned strategy to achieve therapeutic serum levels in a reasonable time frame.

If computed tomography and laboratory work are deemed unnecessary, adequate documentation should support the medical reasoning and clinical findings.

Discussion with the neurology service should be documented with respect to diagnosis, treatment, and close follow-up.

MDMA, 3,4-Methylenedioxymethamphetamine.

BOX 99.8 Admission Criteria for Patients with Seizures

- Change in mental status
  - Drowsiness, coma
- Neurologic deficit
  - Underlying structural condition
  - Tumor, bleeding
- Underlying treatable medical condition
  - Central nervous system infection
- Unable to follow up
- Elderly
- Inability to ambulate
- Lack of social support
- Need for the placement in a facility with a higher level of care

BOX 99.9 Discharge Criteria

- Normal findings on neurologic examination
  - Syncope or cardiogenic cause of loss of consciousness ruled out
  - Trauma ruled out
  - Central nervous system infectious pathology ruled out
  - Toxic and metabolic etiology ruled out
- Patients with chronic seizures
  - Correction of subtherapeutic serum levels
- Reasonable plan for follow-up with neurology service or consultant established

Patients with a chronic seizure disorder can be discharged if they return to their normal baseline neurologic level (Box 99.9). If the drug level is found to be subtherapeutic, an additional dose of antiepileptics should be given prior to discharge. Before discharge, patients may inquire about their prognosis. In the absence of precipitating factors, secondary seizures may be avoidable in the future, but there will always be some risk, depending on the underlying condition and lifestyle. Patients should avoid sleeplessness, heavy alcohol use, and other physiologic stressors that can alter seizure thresholds.
Patients with status epilepticus should be treated aggressively with the administration of multiple medications at once. Clinician should be aware that administration of phenytoin and phenobarbital is rate dependent and that patients may continue to have seizures for 30 minutes before effective serum levels are achieved.

Patients with cocaine abuse, persistent seizures, and a recent history of travel abroad should be evaluated for body packing and decontaminated by whole-bowel irrigation.

Not recognizing that a patient is pregnant (or postpartum) may lead to delayed treatment and obstetrics consultation.

Patients with seizures should be counseled to not drive and should be accompanied because a recurrent seizure is possible.

Timely administration of antibiotics and antiviral medication in patients with central nervous system infection can improve survival and reduce morbidity.

Transient Ischemic Attack and Acute Ischemic Stroke

Holly K. Ledyard

KEY POINTS

- Transient ischemic attack (TIA) is a high-risk warning sign for stroke within 90 days, with the highest risk occurring in the first 2 days.
- Patients with TIA can be accurately risk-stratified for recurrent stroke.
- Large artery atherosclerosis, cardioembolism, and small vessel disease are the leading causes of TIA and acute ischemic stroke.
- Magnetic resonance imaging is valuable in differentiating TIA from acute ischemic stroke.
- The goal of management of patients with TIA is to prevent recurrent stroke with antiplatelet, anticoagulation, or surgical therapy.
- The best outcomes for strokes treated with thrombolytic therapy are found with early delivery of recombinant tissue plasminogen activator (rt-PA) within established guidelines.
- Recent evidence supports extending the time window for treatment of ischemic stroke with rt-PA to 4.5 hours for specific patient populations.
- Stroke units and stroke teams provide comprehensive stroke care that improves patient outcomes.

EPIDEMIOLOGY

The yearly incidence of TIA in the United States has been estimated to be approximately 200,000 to 500,000 but may be higher because of the high frequency of underreporting of these events by medical professionals. 1,6 The annual incidence of TIA may be less and the annual incidence of stroke may be higher if the tissue-based definition were applied to all patients evaluated for TIA. 1,6 It has been estimated that the overall incidence rate of TIA is 1.1 per 1000 U.S. population. 7

This incidence increases with age from 0.1 per 1000 for patients younger than 50 years to 11.7 per 1000 for patients older than 80 years. The incidence of TIA also varies with race and gender: it is significantly greater in blacks and men than in whites and women. The greatest incidence of TIA occurred in black men older than 85 years, who had an incidence of 16 events per 1000. 3

TIAs account for 0.3% of all emergency department (ED) visits, and it is estimated that 8.7% to 30% of patients will have a TIA before stroke. 3,9 Only 28% of TIA patients arrive via ambulance, and 36% of patients arrive during daylight hours. Emergency physicians (EPs) obtain computed tomography (CT) scans on 56% to 70% of all TIA patients and magnetic resonance imaging (MRI) scans on 7% of TIA patients. Nearly half of all patients with TIA are admitted to the hospital, although there is geographic variability in this practice; another 20% of patients are referred for follow-up. Finally, patients seen in the ED with TIA receive preventive aspirin therapy in 18% of cases, other antiplatelet therapy in 7%, and no preventive therapy in an estimated 42%. 7

Clearly defined risk factors for stroke and adverse events following a TIA are now well described in the literature, and several groups of investigators have independently developed short-term risk stratification methods applicable to TIA patients in the ED. 10-13 These investigators reported a 10% rate of stroke in the 90 days following the TIA, with 50% of these strokes occurring in the immediate 48 hours after the TIA.

Recently, the ABCD2 score, which combines elements from existing risk stratification systems, was devised to create a robust prediction standard for determining high-risk populations that will benefit from emergency investigation and therapy to prevent short-term adverse events (Table 100.1). 12

Patients with the following characteristics were at high risk for having a stroke in the next 2 to 90 days: age older than 60 years, blood pressure higher than 140 mm Hg systolic or 90 mm Hg diastolic, clinical features such as unilateral
weakness or speech disturbance, longer duration of symptoms of TIA, and diabetes.

Ischemic stroke accounts for 80% to 88% of the total strokes occurring annually. Each year approximately 795,000 people experience a new or recurrent stroke. It is an important cause of death in the United States and ranks third behind heart disease and cancer.15

Approximately 8% to 12% of all patients suffering an ischemic stroke die within 30 days of the initial stroke. Ischemic stroke disproportionately affects the elderly, with a mean age at onset of 70.5 years. Ischemic stroke affects black and Hispanic populations more frequently than white populations. The age-adjusted incidence of first ischemic stroke per 100,000 population is 88 in whites, 149 in Hispanics, and 191 in blacks.16 Ischemic stroke is an enormous economic burden, with an average 30-day cost of $20,346 for a severe stroke and mean lifetime cost of $140,048.15,17 The United States spends approximately $73.7 billion yearly on the direct and indirect cost of stroke care.15

**FACTS AND FORMULAS**

8.7% to 30% of stroke patients suffer a TIA before the stroke. 10% of TIA patients have a stroke in the next 90 days, 25% to 50% of whom will have their stroke within the first 2 days. 33% of TIA patients with symptoms lasting less than 1 hour will have an infarct shown on diffusion-weighted magnetic resonance imaging. 50% of TIA patients never report symptoms to a physician. 19.2% of patients with untreated symptomatic carotid stenosis of greater than 70% will have a stroke in the next 90 days. For each minute that reperfusion is delayed, 1.9 million neurons die.

TIA, Transient ischemic attack.

**PATHOPHYSIOLOGY**

An ischemic injury involving the central nervous system disrupts normal cerebral blood flow to the brain (40 to 60 mL/100 g brain/min). The extent of injury is based on three principles: the duration of disrupted flow, the flow rate, and collateral circulation. Loss of consciousness occurs within 10 seconds and cell death within minutes of disrupted cerebral circulation.

Cerebral tissues with blood flow between 12 and 20 mL/100 g brain/min are termed the ischemic penumbra. These cells are at risk for permanent injury but have the ability to recover if flow is reestablished. When cerebral blood flow falls below 10 mL/100 g brain/min, electrical activity ceases and cell death occurs. Many areas of the brain may be protected by collateral circulation between the anterior and posterior circulation through vessels that make up the circle of Willis.

Classification of TIAs is important because the pathophysiology and risk for recurrent stroke differ among the subtypes. The five mechanisms described are large artery atherosclerosis, cardioembolism, small vessel disease, other rare determined cause, and undetermined cause.9,18

Large artery atherosclerosis is defined as greater than 50% narrowing of vessel caliber. It accounts for 15% of all ischemic strokes and is the most common cause of low-flow TIA. Symptoms are the result of thrombus formation in a ruptured atherosclerotic plaque. The most commonly affected vascular territories are the origin of the internal carotid and intracranial portion of the internal carotid (siphon), the middle cerebral artery stem, and the junction of the vertebral and basilar arteries. It is found more commonly in men and has a greater incidence in African and Hispanic populations. Patients with large artery atherosclerosis have a higher recurrence rate than do patients with other stroke subtypes: 4%, 12.6%, and 19.2% at 7, 30, and 90 days, respectively.17 These patients have transient or stuttering symptoms in the same vascular territory. Symptoms and disability may be less severe than those in patients with cardioembolic stroke.14

Cardioembolic disease represents 20% to 25% of ischemic cerebrovascular events. The most common sources are abnormal cardiac rhythm, abnormal left ventricular wall motion, and aortic and mitral valve disease.20 The clinical features are...
abrupt in onset, with nonprogressive symptoms that may occur in multiple vascular territories. Cardioemboli affect the anterior circulation in 70% of patients. These patients tend to have more severe symptoms and higher mortality rates; disability is more severe in survivors. Patients with embolic TIA have a lower recurrence rate of 2.5%, 4.6%, 11.9% at 7, 30, and 90 days, respectively.19

Lacunar strokes represent 20% of all ischemic strokes and are caused by small vessel disease—obstruction of the small vessels that penetrate the brain parenchyma at right angles to major parent arteries and supply the basal ganglia, internal capsule, thalamus, and pons.21,22 The vessels most commonly involved are small branches of the middle cerebral and basilar arteries.21 The most common causes of small vessel disease are microatheroma and lipohyalinosis, which are increased in the setting of older age, hypertension, diabetes, and smoking. Small embolic events rarely cause ischemia in these vessels.21,22 Patients with lacunar TIA and stroke commonly have hypertension and diabetes. Black populations are affected more than white populations, and there does not seem to be a gender preference in patients with lacunar infarcts. These patients have a favorable prognosis with low, short-term recurrence rates of 0%, 2%, and 3.4% at 7, 30, and 90 days, respectively.19,21,22

Rare causes of stroke account for approximately 2% to 3% of annual cases. Common causes are nonatherosclerotic vasculopathies (acute arterial dissection, vasculitis, polyarteritis, giant cell arteritis, infectious arteritis), hypercoagulable conditions (deficiencies in proteins C and S and antithrombin III, antiphospholipid antibody syndrome/systemic lupus erythematous, pregnancy, postmenopausal hormone replacement), hematologic disorders (sickle cell disease, polycythemia, myeloproliferative disorders), and other causes of emboli (patent foramen ovale, endocarditis, air).23

Cryptogenic stroke is the designation used for stroke without a well-defined etiology despite extensive evaluation. It accounts for 30% to 40% of all strokes in some stroke databases. Patients with cryptogenic stroke have a better 1-year prognosis than do those with other subtypes; the 2-year risk for recurrence is 14% to 20%.14

Systemic hypoperfusion is an uncommon cause of cerebral ischemia that represents a global decrease in cerebral blood flow. Causes include cardiac arrest and reduced cardiac output as a result of cardiac ischemia, pericardial effusion, arrhythmias, pulmonary emboli, hemorrhage, and medications. Symptoms consist of diffuse brain dysfunction in the setting of unstable vital signs.14,23

**PRESENTING SIGNS AND SYMPTOMS**

Patients who have suffered a TIA often have no physical findings but a variety of historical clinical symptoms. Several studies have demonstrated that interobserver disagreement is high when making the diagnosis of TIA.21,22

A few basic principles can guide accurate diagnosis of TIA. The symptoms are sudden in onset and vascular in nature. TIAs are commonly brief, lasting less than 1 to 2 hours with many lasting less than 10 to 15 minutes. Symptoms are associated with loss of function such as hemiparesis, hemiparesthesia, dysarthria, aphasia, monocular vision loss, diplopia, and gait and balance disturbances. Symptoms such as shaking, scotomata, and marching of symptoms to other body parts are more consistent with migraine or seizure.26

Approximately 80% of ischemic strokes occur in the distribution of the anterior circulation and give rise to deficits in behavior, sensation, movement, and speech, as well as some elements of visual awareness. The minority of strokes occur in the distribution of the posterior circulation. Common posterior circulation symptoms are limb weakness, gait and limb ataxia, oculomotor palsy, and oropharyngeal dysfunction. In addition, patients often exhibit nausea and vomiting because of brainstem involvement, as well as vertigo and balance disorders related to cerebellar and brainstem injury.

**OPHTHALMIC ARTERY**

Transient monocular blindness, known as amaurosis fugax, is caused by transient occlusion of the ophthalmic artery. It is commonly associated with internal carotid artery stenosis and carries a better prognosis than does carotid disease associated with hemispheric TIA.27

**MIDDLE CEREBRAL ARTERY**

Patients with middle cerebral artery occlusion typically exhibit sensory loss hemiplegia, contralateral sensory loss, and contralateral homonymous hemianopia. Patients with dominant hemispheric lesions have aphasia; those with non-dominant hemispheric lesions demonstrate contralateral hemisensory neglect. Subtle findings include gaze preference toward the side of the lesion and contralateral gaze weakness.

**ANTERIOR CEREBRAL ARTERY**

Occlusion of branches of the anterior cerebellar artery is more common than stem lesions and is associated with well-recognized clinical findings: contralateral motor weakness and sensory deficit in the lower extremity. Other symptoms include urinary incontinence because of contralateral weakness of the pelvic floor muscles, memory loss or apathy secondary to occlusion of the orbital or frontopolar branch, dysarthria secondary to compromise of the medial striate artery, and ideomotor apraxia (inability to perform skilled movements) as a result of occlusion of the pericallosal branch.

**SMALL VESSEL DISEASE (LACUNAE)**

Patients with lacunar ischemia are commonly hypertensive, diabetic, or both, and they do not have associated cortical dysfunction (speech, calculation, and spatial orientation deficits). Lacunar infarcts result from ischemic events involving small penetrating branches of the middle cerebral, anterior cerebral, posterior cerebral, and basilar and anterior choroidal arteries. These lesions affect the basal ganglia, internal capsule, thalamus, putamen, and internal capsule. Five major lacunar syndromes are recognized: pure motor hemiparesis, ataxic hemiparesis, pure sensory syndrome, mixed sensorimotor syndrome, and dysarthria–clumsy hand syndrome.

Pure motor hemiparesis is the most common lacunar syndrome and occurs in 50% of patients with lacunar strokes. Patients have stuttering symptoms that develop over hours, as well as contralateral facial and arm weakness, but do not have sensory or higher cortical dysfunction. The injury involves the corona radiata or internal capsule.22

Ataxic hemiparesis syndrome is characterized by weakness and dysmetria (inability to fix the range of movement) on the
same side. The lower extremity is more often affected and the face is least affected. The injury involves the internal capsule, basis pontis, or corona radiata.\textsuperscript{22}

Patients with pure sensory syndrome have contralateral sensory loss in the face, arm, and leg. Symptoms include sensory ataxia, a movement disorder secondary to sensory impairment; a wide-stance gait with gaze directed to the feet; and a walking pattern characterized by a stamping action that maximizes any remaining proprioception. The injury involves the ventral posterior nucleus of the thalamus.\textsuperscript{22}

In mixed sensorimotor syndrome, patients have hemiparesis or hemiplegia associated with sensory loss on the same side. This syndrome is distinguished from the other syndromes by the lack of associated cortical symptoms. The posterolateral thalamus and the posterior limb of the internal capsule are the sites of injury.\textsuperscript{22}

Dysarthria–clumsy hand syndrome is the least common of the lacunar syndromes and affects 6\% of patients with lacunar stroke. Patients are typically dysarthric secondary to paresis of the lip, tongue, and jaw musculature and report clumsiness of hand movement. The injury involves fibers descending through the genu of the internal capsule.\textsuperscript{22}

**VERTIBROBASILAR ARTERIES**

Twenty percent of ischemic events affect brain tissue supplied by the posterior circulation. Patients with posterior circulation ischemia rarely have a single initial sign or symptom. Typical symptoms are dizziness, vertigo, headache, vomiting, double vision, loss of vision, transient interruption of consciousness, numbness, weakness, and ataxia. These patients often have crossed signs that include ipsilateral cranial nerve deficits associated with contralateral motor deficits. The most common signs include contralateral limb weakness, gait and limb ataxia, oculomotor palsy, and oropharyngeal dysfunction.

**POSTERIOR CEREBRAL ARTERY**

Occlusion of the posterior cerebral artery and its branches leads to a variety of defects in the cerebral cortex, midbrain, thalamus, subthalamic nuclei, and corpus callosum. Stem lesions in the posterior cerebral artery cause isolated contralateral homonymous hemianopia. Midbrain lesions result in crossed symptoms with ipsilateral third nerve palsy accompanied by contralateral motor hemiplegia. Thalamic branch lesions cause contralateral sensory loss accompanied by hemianopia. Injury to the subthalamic nuclei results in ballism of the contralateral arm. Finally, corpus callosum injury results in an inability to transfer written information from right to left, as well as alexia (inability to read written material).\textsuperscript{23}

**CEREBELLAR INFARCT**

The most common cause of an ischemic injury involving the cerebellum is an embolic infarct in the upper part of the cerebellum. Symptoms include dizziness, vertigo, vomiting, blurred vision, and difficulty walking. Patients may report that they veer to a specific side or are unable to sit upright without assistance. Cerebellar infarcts are distinguished from infarcts in other anatomic locations by the lack of hemiparesis or hemisensory deficits.\textsuperscript{23,28} Hypotonia may be present in the arm on the affected side. This sign is best elicited by having patients hold their arms straight out at 90 degrees from the trunk, quickly lower them, and then abruptly stop the lowering motion. The affected side is detected because the hypotonic arm will overshoot the rapid descent.

**LATERAL MEDULLARY SYNDROME (WALLENBERG SYNDROME)**

Occlusion or narrowing of the intracranial vertebral artery causes signs and symptoms related to ischemic injury to the lateral medullary tegmentum. Symptoms include ipsilateral facial sensory loss, ataxia, and nystagmus. Patients may also have Horner syndrome, hoarseness, difficulty swallowing, and contralateral hemisensory loss of pain and temperature sense.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Evaluation of patients with suspected ischemic injury is summarized in Box 100.1. The results of these fundamental tests combined with risk stratification can guide the EP in determining whether cerebral injury has occurred, as well as the cause of the ischemia.

Patients with TIA and ischemic stroke require rapid and accurate diagnosis to determine the cause and location of the event and the extent of damage. This knowledge allows the EP to estimate the risks and benefits associated with therapies that will reestablish cerebral blood flow and preserve viable brain tissue.

Rapid diagnosis of acute ischemic stroke begins with public education about recognition of the major warning signs of stroke. Prehospital personnel also play a crucial role in early diagnosis and rapid transport of stroke patients to treatment facilities. Tools such as the Cincinnati Prehospital Stroke Scale and the Los Angeles Prehospital Stroke Screen (LAPSS) are used to evaluate facial droop, arm weakness, and speech abnormalities in patients with suspected stroke. In addition, the LAPSS screens for mimics of stroke such as hypoglycemia, hyperglycemia, and seizure and has high sensitivity (93\%) and specificity (97\%) for the diagnosis of acute stroke.\textsuperscript{29,30}

EPs caring for patients with acute ischemic stroke are often under enormous time constraints. A systematic method is necessary to distinguish patients with stroke from those with conditions that mimic stroke.\textsuperscript{31} In addition, the EP must combine historical and physical data with the results of

</table>
neurologic imaging to exclude hemorrhage and determine the extent of injury. These elements, coupled with basic laboratory tests and an electrocardiogram (ECG), as recommended by the American Heart Association (AHA), are the foundation for accurate diagnosis of an acute ischemic stroke.

The history is the cornerstone of accurate stroke diagnosis. Historical evidence that has been identified as being predictive of a patient having a stroke includes persistent focal neurologic deficits, acute onset during the previous week, and no history of head trauma. Clinical symptoms such as arm and leg weakness and speech impairment are more reliable indicators than subjective isolated sensory symptoms are. The single most important piece of historical information is the time of onset of the symptoms. This is considered to be the last time that the patient was at the previous baseline or symptom-free state. For patients unable to provide this information or awaken with stroke symptoms, onset is defined as time when the patient was last seen to be normal. Other key historical factors include contraindications to thrombolytic therapy, medications being taken by the patient, heart disease, previous stroke, TIA, seizures, vomiting, or headache occurring at the beginning of the patient’s acute symptoms.

EPs must use a reproducible standardized physical examination to assess the severity of injury in stroke patients. Three key physical findings—facial paresis, arm drift, and abnormal speech—are highly predictive of an acute stroke. The National Institutes of Health Stroke Scale (NIHSS) (see the Documentation box) is a valid, standardized tool that records clinical findings and provides information that is helpful in determining the prognosis and therapeutic options. This 42-point scale evaluates level of consciousness, cranial nerves, motor function, ataxia, sensation, speech, and neglect. It can be used for serial examinations and is a predictor of patient outcome and risk associated with therapy, which can be useful when discussing treatment options with specialists, patients, and family members.

Patients with an NIHSS score lower than 6 have a predicted excellent outcome at 6 months, and 81% are discharged home. Nearly half the patients with an NIHSS score higher than 15 will require transfer to a nursing facility. Patients with an NIHSS score higher than 20 have a 17% risk for intracerebral hemorrhage when treated with recombinant tissue plasminogen activator (rt-PA). Finally, each additional point on the NIHSS decreases the likelihood of an excellent outcome by 17%.  

Although the history and physical examination are important elements in making an accurate diagnosis of patients with acute neurovascular events, neuroimaging is the key diagnostic tool. The goals of modern neuroimaging evaluation are to (1) obtain evidence of a vascular origin of the symptoms; (2) exclude an alternative nonischemic origin; (3) ascertain the underlying vascular mechanism of the event, which helps guide therapy; (4) identify prognostic outcome categories; and (5) improve selection of patients to be treated with reperfusion therapies by identifying those with regions of salvageable brain tissue, low risk for hemorrhagic transformation, or occlusion of large arteries that might be amenable to therapy. Currently, EPs have a multitude of imaging options that are based on availability of the imaging modality and local expertise in interpretation of the images.

Non–contrast-enhanced CT remains the standard imaging technique for evaluating patients with acute stroke. It can be performed in the majority of hospitals, images are acquired rapidly, and it is sensitive in detecting acute hemorrhage. For patients with TIA, CT has been shown to provide an alternative diagnosis in 1% of all cases, and a new infarct has been found within 48 hours in 4% of patients with TIA. Of these patients, 38% eventually experienced a new ischemic stroke in the next 90 days. CT findings not associated with an increased short-term risk for stroke include old infarction, periventricular white matter disease, cerebral atrophy, and vascular calcification. Unfortunately, CT scans are frequently negative in the first hours after an ischemic stroke, are limited in defining posterior fossa structures and discriminating between infarct and viable at-risk tissue (penumbra), and provide no information on the presence or location of vascular pathology.

Subtle clues found on CT scanning are cortical hypodensity, hyperdense middle cerebral artery, middle cerebral artery dot sign, sulcal effacement, hypointensity of the insular ribbon, and obscuration of the lentiform nucleus. The Alberta Stroke Program Early CT Score (ASPECTS) organized these early subtle clues into a semiquantitative 10-point grading system for early ischemic changes in the middle cerebral artery territory found on CT scans. Patients with an ASPECTS higher than 7 were found to have a much higher incidence of parenchymal hematoma after receiving rt-PA therapy.

Perfusion CT is an advanced neuroimaging technique that uses intravenous (IV) contrast material to provide semiquantitative information on cerebral blood flow and cerebral blood volume. Other useful calculations include the mean transit time of the contrast agent from the arterial to the venous circulation and time to peak, which measures the time between the first arrival of contrast agent in the artery and the peak of the bolus within the brain tissue. Studies suggest that a CT battery that includes non–contrast-enhanced CT, CT angiography, and CT perfusion can be performed quickly in patients with acute stroke and can provide comprehensive

**DOCUMENTATION**

- Time of onset of symptoms or the last time that patient was seen to be normal
- Initial National Institutes of Health Stroke Scale (NIHSS) score
- Resolution of symptoms and NIHSS score of 0 for patients with a transient ischemic attack (TIA)
- Single or multiple events
- History of stroke risk factors
- Current medications, including antplatelet drugs and anticoagulants
- Results of cerebral imaging
- ABCD2 score for patients with TIA
- Suspected cause and initiation of preventive or thrombolytic therapy
- Specialist consultation and early (within 48 hours) follow-up for low-risk patients with T IA discharged from the emergency department
- Specialist consultation and admission to a stroke unit for patients with stroke
The goal of management of patients with TIA is the introduction of therapy that will prevent stroke and thus avoid permanent disability and untimely death. Three types of medical therapy to achieve this goal are available: antiplatelet therapy, anticoagulation therapy, and surgical or endovascular therapy. In addition, patients should be instructed about measures that modify risk factors for stroke.

ED management of patients with acute ischemic stroke requires a team approach that is organized, time sensitive, and goal directed. The goal of ED care is to ensure medical stability, identify the cause of the ischemic event, determine the extent of injury, and create a therapeutic plan that reestablishes cerebral function and prevents or limits further injury. Four time goals for therapy have been established (see the Priority Actions box).

**ANTIPLATELET THERAPY**

The use of antiplatelet agents rather than oral anticoagulation is the treatment of choice for the prevention of stroke in patients with TIA secondary to atherothrombotic disease (Box 100.2). Aspirin is the most widely used and the most economical drug available for prevention of stroke. Currently,
clopidogrel, ticlopidine, and combined dipyridamole-aspirin (DPA) are antiplatelet agents that are effective alternatives to aspirin. Unfortunately, despite being the standard of care in the AHA guidelines, these agents are often underused, with only 18% of TIA patients encountered in the ED receiving aspirin, 7% receiving other antiplatelet agents, and 42% receiving no treatment.7

Aspirin is a mainstay of antiplatelet therapy for prevention of atherothrombotic stroke in TIA patients. It achieves this benefit through irreversible block of the enzyme cyclooxygenase, which in turn prevents the metabolism of arachidonic acid to the potent vasoconstrictor and platelet aggregator thromboxane A2. The effective dose of aspirin is 50 to 325 mg/day. It is associated with an overall reduction of 15% to 18% in the combined end points of stroke, myocardial infarction, and death.47 It is well tolerated and inexpensive; however, gastrointestinal bleeding is a documented major side effect.

Clopidogrel (75 mg daily) and ticlopidine (250 mg twice daily) are adenosine diphosphate receptor antagonists that prevent platelet aggregation. Clopidogrel has the advantages of once-daily dosing, less neutropenia, and fewer gastrointestinal side effects. It must be noted that clopidogrel has been reported to induce thrombotic thrombocytopenic purpura in a very small percentage of patients.48 In addition, clopidogrel has not been compared with placebo for secondary stroke prevention.49

Large, multicenter randomized controlled trials have compared clopidogrel with aspirin50 and combined clopidogrel-aspirin with clopidogrel alone in the prevention of stroke, myocardial infarction, and death.51 Subgroup analysis failed to find a statistically significant reduction in ischemic stroke in favor of clopidogrel or the combined drugs. In addition, no increase in reduction of the risk for stroke was achieved by giving aspirin to symptomatic patients currently taking clopidogrel; in fact, major bleeding increased with the combination of the two drugs.52 Clopidogrel remains a viable option for patients who are aspirin sensitive, and it has been shown to be beneficial in patients who have concomitant cerebral vascular and coronary disease or recent stent placement.

Dipyridamole is a cyclic nucleotide phosphodiesterase inhibitor that inhibits platelet aggregation by increasing levels of cyclic adenosine monophosphate. Extended-release dipyridamole in combination with aspirin has been shown to reduce the risk for stroke by 37% when compared with placebo and to reduce risk by 23% when compared with aspirin alone.53 Studies comparing extended-release DPA and clopidogrel have demonstrated that they are not different in their efficacy.54 Common side effects include headache and gastrointestinal disturbances.

**ANTICOAGULATION**

Atrial fibrillation (AF) is responsible for 50% of all cardioembolic events. Patients with a TIA or ischemic stroke and paroxysmal or sustained AF should receive warfarin as the therapy of choice for the prevention of stroke.46,53 These patients have a target INR of 2.5 (range, 2.0 to 3.0). Risk factors for stroke in patients with AF include congestive heart failure, hypertension, age older than 75 years, diabetes, and previous stroke or TIA.54 For these high-risk patients who require temporary interruption of oral anticoagulation, bridging therapy with low-molecular-weight heparin administered subcutaneously is reasonable.46

Other cardiac risk factors include left ventricular thrombus in the setting of acute myocardial infarction, native valvular heart disease, and prosthetic heart valves. Warfarin is a reasonable option for all these conditions with slight variations. With a left ventricular thrombus, oral anticoagulation with a target INR of 2.5 (range, 2.0 to 3.0) should be continued for at least 3 months. In the setting of rheumatic mitral valve disease, oral anticoagulation with a similar target is also reasonable. Because of the increased risk for stroke in patients with mechanical prosthetic heart valves, the target range for anticoagulation is increased and the target INR should be 3.0 (range, 2.5 to 3.5). Patients with bioprosthetic valves can be maintained at an INR of 2.5 (range, 2.0 to 3.0). In general, to avoid additional bleeding risk, antiplatelet agents should not be routinely added to warfarin unless a patient with a prosthetic heart valve has an ischemic stroke or systemic embolism despite adequate therapy with oral anticoagulants and is not at high risk for bleeding.46 Warfarin has not been shown to be superior to aspirin in the prevention of noncardioembolic forms of stroke.55

**SURGICAL MANAGEMENT**

Carotid endarterectomy (CEA) performed in patients with symptomatic severe carotid stenosis greater than 70% to 99% results in a long-term benefit in preventing strokes.56-58 Patients with symptomatic stenosis of 50% to 69% may also benefit from CEA, depending on age, sex, and comorbid conditions, if their perioperative risk for morbidity and mortality is estimated to be less than 6%.59 Finally, CEA is not beneficial or is harmful in symptomatic patients with stenosis of less than 50% (Box 100.3).39-41 When performed within 2 weeks, surgery is reasonable in patients with no contraindications to early revascularization.46

Recently, carotid angioplasty plus stenting (CAS) has been deemed a possible alternative to surgical carotid therapy and has been shown to have outcomes comparable with those achieved with CEA.62-64 The AHA now recommends CAS as...
an alternative to CEA for symptomatic patients at average or low risk for complications associated with endovascular intervention when the diameter of the lumen of the internal carotid artery is found to be reduced by more than 70% by noninvasive imaging or by more than 50% by catheter angiography, and CAS can be used in patients with greater than 70% stenosis if the stenosis is difficult to access surgically or if they are deemed to be poor surgical candidates.

**RISK FACTOR REDUCTION**

Several factors portend an increased risk for stroke in patients who have experienced a TIA. Modifiable risk factors include hypertension, diabetes, hyperlipidemia, cigarette smoking, and heavy alcohol consumption. The AHA recommends that blood pressure be reduced in all patients with TIA beyond the first 24 hours of symptoms, with an average reduction of approximately 10/5 mm Hg and an ultimate goal of less than 120/80 mm Hg. Reduction of blood pressure can be attained through lifestyle modification and antihypertensive therapy. In diabetic patients, diet, exercise, oral hypoglycemic drugs, and insulin are recommended to gain glycemic control.

Elevations in total cholesterol or low-density lipoprotein cholesterol (LDL-C) and low levels of high-density lipoprotein cholesterol (HDL-C) are modest risk factors for stroke. A metaanalysis of statin trials showed that the larger the reduction in LDL-C, the greater the reduction in risk for stroke. Therefore, the AHA recommends statin therapy with intensive lipid-lowering effects in patients with TIA who have evidence of atherosclerosis and an LDL-C level higher than 100 mg/dL. It is reasonable to target a reduction of at least 50% or levels of less than 70 mg/dL. For patients with TIA and low HDL-C, treatment with niacin or gemfibrozil can be considered.

Additional lifestyle risk factor reduction includes providing TIA patients with smoking cessation counseling and advising patients to avoid environmental (passive) tobacco smoke. Patients who are heavy drinkers should eliminate or reduce their consumption of alcohol to no more than two drinks per day for men and one drink per day for women who are not pregnant.

**THROMBOLYSIS**

The only treatment of acute ischemic stroke approved by the Food and Drug Administration (FDA) is IV rt-PA therapy, which has traditionally been recommended for carefully selected patients older than 18 years who are seen within 3 hours of the onset of an acute ischemic stroke. There have been some recent updates to recommendations for the use of IV rt-PA outside the traditional 3-hour time window, as well as the use of intraarterial thrombolysis for patients initially seen between 3 and 6 hours after the onset of symptoms.

Adjuncts to intraarterial thrombolysis include angioplasty, stenting, and clot retrieval devices. Other therapies include prevention of hypoxemia and dehydration, administration of antiplatelet and anticoagulation agents, normalization of glucose, and temperature control.

The era of emergency intravenous thrombolysis for acute ischemic stroke began in 1995 with the National Institute of Neurological Disorders and Stroke (NINDS) rt-PA trial. This study was a single randomized controlled trial that compared patients with ischemic stroke treated with IV rt-PA versus placebo (given at 0 to 90, 90 to 180, and 0 to 180 minutes). Despite no difference in the NIHSS score at 24 hours, the main outcome of the trial was a 30% decrease in disability at 3 months in patients treated with IV rt-PA versus 20% in those treated with placebo. This benefit was similar 1 year after stroke. Adverse events included a 10-fold increase in the rate of intracerebral hemorrhage 36 hours after treatment with rt-PA (6% versus 0.6%); however, the death rate in the two treatment groups was similar at 3 months (17% versus 20%) and at 1 year (24% versus 28%).

Concern over data that support the use of thrombolitics for acute ischemic stroke and external validity in community hospitals has been raised by some EPs. Some community hospital groups have reported high rates of intracranial hemorrhage and fewer favorable outcomes. In these studies the risk for hemorrhage is proportional to the degree to which the hospital groups have reported high rates of intracranial hemorrhage and fewer favorable outcomes. In these studies the risk for hemorrhage is proportional to the degree to which the NINDS protocol is not followed. Critics also observed that the relative predominance of mild strokes (NIHSS score < 5) with a probably good outcome in the rt-PA group may explain the entire benefit reported in patients treated between 91 and 180 minutes. Neither reanalysis of the data by the NINDS study group nor a separate analysis by an independent group could demonstrate that the effect of the imbalance in severity influenced the overall result that rt-PA therapy positively influenced outcome. Several recent studies also demonstrated improved neurologic outcomes and similar hemorrhage rates as the original NINDS data.

The effectiveness of thrombolysis is determined by several variables. Time until treatment is extremely important: 75% of patients in one pooled analysis who were treated within 60 minutes of the onset of stroke in the initial pooled analysis...
had the best chance of achieving complete or partial reopening of the occluded artery.\(^6\) Patients with mild to moderate strokes (NIHSS score < 20) and patients younger than 75 years had the greatest potential for a favorable response to treatment.\(^6\) Predictors of a poor postthrombolysis prognosis include older patient age, higher stroke severity (NIHSS score > 22), systemic hypertension or hypotension, hyperglycemia, and fever.

Despite its effectiveness in improving neurologic outcomes, the majority of patients with ischemic stroke are not treated with rt-PA, largely because they arrive after the 3-hour window for treatment. One potential solution would be to designate a longer time window for treatment. A pooled analysis of previous large trials suggested that the upper limit of the treatment window may be as late as 5 to 6 hours.\(^7\) The ECASS-3 trial enrolled patients to either rt-PA or placebo by using the current guideline protocols of between 3 and 4.5 hours after the onset of symptoms. It excluded patients older than 80 years, those taking oral anticoagulants, those with a history of both previous stroke and diabetes, and patients with a baseline NIHSS score higher than 25. The rate of symptomatic intracranial hemorrhage (as defined by NINDS criteria) was 7.9% for the treatment group and 3.5% for the placebo group, neurologic improvement was significantly higher in the rt-PA group than in the placebo group, and mortality in the two treatment groups did not differ significantly.\(^6\) These findings are consistent with the results in this time window from pooled analyses of previous trials.\(^7\) Subsequently, the AHA made recommendations regarding expansion of the time window for the treatment of ischemic stroke with IV rt-PA (Box 100.4).\(^8\)

Centers that care for stroke patients must develop guidelines for the appropriate selection of patients and develop systems to rapidly deliver thrombolysis therapy to these patients. Candidates for IV thrombolysis must have a clearly defined time of symptom onset of less than 270 minutes, must be older than 18 years, and must have no contraindications to thrombolytic therapy (Box 100.5).\(^9\) The dosing regimen is 0.9 mg/kg (maximum of 90 mg) of rt-PA, with 10% (maximum of 9 mg) given as a bolus over a 1- to 2-minute period, followed by the remaining dose (maximum of 81 mg) infused by pump over a 1-hour period. Any indwelling catheters should be placed before the administration of thrombolytics. The patient should be admitted to an intensive care or stroke unit for frequent neurologic examination and blood pressure checks, with the goal of maintaining blood pressure lower than 180/105 mm Hg. If severe headache, acute hypertension, nausea, or vomiting develops, the infusion should be discontinued and an emergency non–contrast-enhanced head CT scan should be obtained. The institution must have a protocol for the management of thrombolytic-induced intracerebral hemorrhage. The patient should not receive aspirin or heparin during the first 24 hours after thrombolytic therapy. A follow-up non–contrast-enhanced head CT scan should be done at 24 hours and before starting anticoagulant or antiplatelet therapy.\(^3\)

## ENDOVASCULAR PROCEDURES

Procedures such as intraarterial thrombolysis with or without mechanical embolectomy, angioplasty, and carotid stenting are considered experimental therapies that may benefit

---

**BOX 100.4 Recommendations of the American Heart Association Regarding Extension of the Time Window for Administration of Recombinant Tissue Plasminogen Activator in Patients with Ischemic Stroke**

Recombinant tissue plasminogen activator should be administered to eligible patients who can be treated in the 3- to 4.5-hour period after the onset of stroke. Exclusion criteria for the extended treatment window include:

- Patients older than 80 years
- Baseline National Institutes of Health Stroke Scale score higher than 25
- Patients with a history of both stroke and diabetes
- All patients receiving oral anticoagulants regardless of their international normalized ratio

Delays in evaluation and initiation of therapy should be avoided because of the opportunity for greater neurologic improvement with earlier treatment.

---

**BOX 100.5 Contraindications to Administration of Recombinant Tissue Plasminogen Activator**

- Head trauma or stroke in the previous 3 months
- Myocardial infarction in the previous 3 months
- Gastrointestinal or urinary tract hemorrhage in the previous 3 weeks
- Major surgery in the past 2 weeks
- Arterial puncture at a noncompressible site in the previous 7 days
- History of previous intracranial hemorrhage
- Systolic blood pressure higher than 185 mm Hg, diastolic blood pressure higher than 110 mm Hg
- Evidence of active bleeding or acute trauma (fracture) on examination
- Oral anticoagulation with an international normalized ratio higher than 1.7
- Receiving heparin in the previous 48 hours with an abnormal activated partial thromboplastin time
- Platelet count lower than 100,000/mm\(^3\)
- Blood glucose level lower than 50 mg/dL
- Seizure with postictal residual neurologic impairments
- Computed tomography scan demonstrating multilobar infarction (hypodensity in more than a third of the cerebral hemisphere)

specific patient groups who are seen outside the 3-hour window or have contraindications to IV thrombolysis, such as recent surgery. Benefits of this therapy include a lower dose of thrombolytic, direct visualization of the occluded vessel, and higher recanalization rates. The FDA has approved use of the MERCI (Mechanical Embolus Removal in Cerebral Embolism) devise. Treatment requires the patient to be at an experienced stroke center with immediate access to cerebral angiography and qualified interventionalists.

**ADJUVANT THERAPIES**

**Blood Pressure Management**

Management of blood pressure in an acute stroke patient is controversial. In an ED study of patients with acute ischemic stroke, systolic blood pressure outside the range of 155 to 220 mm Hg and diastolic blood pressure outside the range of 71 to 105 mm Hg were associated with increased 90-day mortality. These findings demonstrate the harmful effects of both hypertension and hypotension and indicate that there is an optimal range of blood pressure required to perfuse at-risk tissue in these patients.

Current American Stroke Association and European Stroke Initiative guidelines recommend withholding antihypertensive therapy in patients with acute ischemic stroke unless they are thrombolysis candidates or show evidence of end-organ dysfunction (acute myocardial infarction, aortic dissection, pulmonary edema, and renal failure). Short-acting IV medications with reliable dose response and safety profiles should be used. Medications that meet these requirements include labetalol, nicardipine, and esmolol. Despite concern that lowering blood pressure in the acute stroke setting might be harmful, pilot data from the CHHIPS trial demonstrated that labetalol and lisinopril are effective antihypertensive drugs for patients with acute stroke and do not increase serious adverse events. Early lowering of blood pressure also resulted in a reduction in mortality. However, in view of the small sample size, care must be taken when these results are interpreted, and further evaluation in larger trials is needed. Conversely, small clinical studies suggest that drug-induced hypertension could be used in the management of some patients with acute ischemic stroke to improve cerebral blood flow, but data from large clinical trials are lacking. The AHA recommends using this method only in exceptional cases or within the setting of clinical trials.

**Glucose Management**

Hyperglycemia (glucose > 185 mg/dL) and hypoglycemia (glucose < 60 mg/dL) are associated with worsening of clinical and tissue outcome in patients with acute ischemic stroke. Hyperglycemia can accelerate the course of ischemic injury, actively convert penumbra to infarcted tissue, and increase the risk for hemorrhagic events and poor outcome in patients receiving rt-PA therapy. Glycemic control with rapidly acting insulin should be instituted to maintain blood glucose between the suggested levels of 140 to 185 mg/dL while taking care to avoid hypoglycemia.

**Temperature Management**

Hyperpyrexia (temperature > 38.0° C) is associated with increased morbidity and mortality. The pathologic effects stem from increased neurotransmitter and free radical production and adverse effects on the blood-brain barrier, which seem to be most pronounced at the border zone or penumbra of the infarct and lead to loss of potentially viable tissue. Therefore, the source of the fever should be actively sought and treated with acetaminophen.

**Anticoagulation**

Currently, early administration of heparin is not recommended for any type of acute ischemic stroke because of the increased risk for secondary hemorrhagic conversion; furthermore, clinical trial data have shown no reduction in stroke recurrence or improvement in patient outcome. Additionally, initiation of anticoagulant therapy within 24 hours of treatment with IV rt-PA is not recommended.

**Antiplatelet Therapy**

The goals of antiplatelet therapy in patients with stroke are a reduction in stroke recurrence and stroke-related morbidity and mortality. Aspirin (50 to 325 mg/day) therapy resulted in a significant reduction in death and disability when given within 48 hours of ischemic stroke. It reduced the risk for early recurrent stroke in all stroke subtypes. Therefore, patients who are not aspirin sensitive or at risk for aspiration and are not being administered t-PA should receive aspirin within 48 hours of ischemic stroke.

Other oral antiplatelet agents, including clopidogrel, ticlopidine, and combination drugs such as DPA, have not been proved to be safer or more cost-effective than aspirin alone. Clopidogrel is recommended for aspirin-sensitive patients who require emergency antiplatelet therapy in the ED. The use of IV antiplatelet agents such as glycoprotein IIb/IIIa inhibitors is still investigational and is not recommended for use outside the setting of clinical trials.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

The areas that should be emphasized when making decisions regarding admission or discharge are the completeness of the evaluation, the source of the event, and resolution of the symptoms. These issues, coupled with proper risk stratification and cerebral vascular imaging, represent a logical approach to achieving safe and proper disposition of the patient.

A thorough diagnostic evaluation that determines the cause of the TIA plays a crucial role in the decision to hospitalize or discharge patients from the ED. Patients who are at high risk for recurrent events and are unable to undergo appropriate cerebral and vascular imaging should be hospitalized to expedite the evaluation and allow observation for recurrent events in the period of vulnerability (hours or days) after the event. Diagnostic benefits of hospital admission include rapid evaluation, monitoring for acute neurologic deterioration, and cardiac telemetry monitoring. Therapeutic benefits include the ability to deliver thrombolytic therapy, rapid institution of antiplatelet and anticoagulation therapy, and early consideration for carotid surgery.

The AHA has recently recommended hospital admission for patients initially seen with TIA within 72 hours of the event and when any of the following criteria are present: (1) ABCD2 score higher than 3, (2) ABCD2 score of 0 to 2 and
uncertainty that diagnostic work-up can be completed within 2 days as an outpatient, and (3) ABCD2 score of 0 to 2 and other evidence indicating that the patient’s event was caused by focal ischemia.¹

Patients deemed to be at low risk after a complete evaluation and those who have a clear cause and are receiving preventive therapy can be discharged after appropriate consultation with a neurologist, cardiologist, or vascular surgeon. It should be emphasized to all patients that a TIA is a high-risk event and that the risk for stroke is highest in the next 2 to 90 days (see the Patient Teaching Tips box). All patients discharged from the ED should be scheduled for follow-up during the next 2 days, which is the most critical period for recurrent events. Preventive therapy, especially antiplatelet therapy, should be initiated before discharge.¹

**PATIENT TEACHING TIPS**

A transient ischemic attack is a serious warning sign for stroke, myocardial infarction, and death in the next 2 to 90 days. Patients should understand the warning signs of stroke and be instructed to return to the emergency department if symptoms recur. Patients with significant carotid disease should be evaluated promptly for surgery within the next 2 weeks and should be treated with antiplatelet agents. Patients who are discharged should have early outpatient follow-up and evaluation in the following 2 to 7 days. Patients should control modifiable risk factors and adhere to antiplatelet, anticoagulation, and antihypertensive therapy.

Unlike TIA, all patients with acute ischemic stroke require admission to the hospital to be observed for changes in their condition, facilitate medical or surgical procedures, receive preventive therapy, and recover neurologic function with rehabilitative services. Optimal disposition is dependent on local hospital expertise, severity of the stroke, and intensity of therapy. Following early therapy initiated at a community hospital, patients may be transferred to a stroke center for more comprehensive care, which is often coordinated by stroke teams in hospitals throughout the United States. Patients undergoing thrombolysis should have access to the intensive care unit, neurology and neurosurgery consultation, and blood bank services.

Admission to a stroke unit has been validated in clinical trials as being statistically significant in decreasing disability and mortality while increasing the probability that the patient will return home and resume daily living activities.⁶ These effects are independent of age, sex, and severity of stroke and are reproducible in a community setting.

Intensive monitoring in a stroke unit allows early detection and treatment of fever, hypoxemia, hyperglycemia, and cardiac rhythm disturbances and permits early mobilization coupled with physical and occupational therapy. Stroke units have been found to be effective for patients with large artery–associated stroke and more costly but equally efficacious as medical ward care for patients with small vessel–associated stroke.⁷

Hospitals without stroke units should have comprehensive protocols and quality assurance programs that actively manage the variables shown to affect outcome and ensure optimal care for all patients.

Patients who require intensive care unit admission are those with severe stroke and the potential for decompensation. High-risk populations include patients treated with IV or intraarterial thrombolysis or catheter-based therapies, patients with an NIHSS score higher than 17, and patients with large strokes in the cerebellar or middle cerebral artery distribution who are at risk for the development of cerebral edema.

**TIPS AND TRICKS**

Use diffusion-weighted magnetic resonance imaging to differentiate a true transient ischemic attack from ischemic stroke.

Use risk stratification criteria to determine the need for hospitalization.

Patients with motor and speech deficits and prolonged symptoms are more likely to have positive findings on diffusion-weighted imaging.

An antiplatelet agent should be prescribed for patients with transient ischemic attacks to minimize the risk for stroke.

A stroke team or neurologist should be consulted early for patients who may be candidates for thrombolytic therapy.

Patients with acute stroke should be admitted to a stroke unit for further care.

SECTION IX 
NEUROVASCULAR DYSFUNCTION 

The sensation of headache is rarely due to injury to the brain parenchyma itself. Rather, head pain results from tension, traction, distention, dilation, or inflammation of pain-sensitive structures external to the skull, portions of the dura mater, and blood vessels. Each of these mechanisms is probably mediated by a final common biochemical pathway that results in pain; therefore, a favorable response to analgesics should not be used to judge the cause of an individual headache.1

EPs should develop a logical, practical, and accurate approach to identification of patients with serious pathology. A comprehensive organizational scheme developed by the International Headache Society has recently been updated (Table 101.1); however, this scheme is cumbersome in emergency practice. For practical purposes, headaches can be divided into “benign” and “cannot miss” categories (Table 101.2).

Treatment of pain should occur in parallel with the history and physical examination. Appropriate analgesia is all that most patients require, and comfortable patients are more willing to undergo tests and procedures (e.g., lumbar puncture [LP]). Immediate pain control results in greater patient satisfaction and more rapid disposition. That said, a given patient’s response to analgesics should not alter the diagnostic strategy, so there is no reason to withhold treatment.

Evaluation should focus on signs and symptoms that can differentiate a benign headache from one requiring emergency work-up and treatment. For example, although location of the headache is often considered significant, unilateral headache is a hallmark of both primary (migraine, cluster) and secondary (intracerebral hemorrhage, glaucoma) headaches, thus limiting its usefulness in diagnosis. In contrast, fever and neck stiffness are uncommon with primary headache and are therefore very useful.

Identifying the timing and duration of the headache is useful. Questions such as “What brings you here today rather than any other day?” can help focus patients on the timing of their symptoms. Worrisome features include a new acute headache.
or a subacute headache that is increasing in severity. An abrupt or “thunderclap” onset suggests intracranial hemorrhage or cerebral venous sinus thrombosis. If the maximum intensity of the pain occurred at the onset, aneurysmal bleeding should be considered. Very fleeting headaches, termed “jabs and jolts,” that last seconds are typically benign. In abrupt-onset headaches, the activity at the onset sometimes suggests the cause, such as with coital headache or benign exertional headache. However, even though a history of these activities can be a sensitive indicator of the corresponding diagnoses, specificity is poor. Therefore, subarachnoid hemorrhage cannot be excluded on the basis of activity before the headache.

LOCATION
Location of the pain is not very helpful in diagnosing headaches because of the significant overlap between benign and serious causes. Some recommend work-up of patients whose headaches always occur on the same side.

SEVERITY
Severity of the pain also has limitations in differentiating benign from serious headaches. Although the “worst-of-my-life” headache suggests a more serious problem, most severe headaches seen in the ED have benign causes. Patients without a previous history of similar, severe headaches should be evaluated for a secondary cause of the headache. In patients with a history of previous headaches, ask about details and consider evaluating those whose headaches are clearly increased in severity or different in quality.

QUALITY
The quality of the patient’s pain is critical. Most secondary headaches are qualitatively unique, unusual, or distinctly different from prior headaches. Diagnostic work-up of patients with chronic headaches that have new or unusual features should be strongly considered.

ASSOCIATED SYMPTOMS
Specific associated symptoms can provide important clues to a dangerous cause of the headache. Fever and neck stiffness suggest meningitis. Syncope, seizure, or any focal neurologic symptoms or new signs associated with a headache should prompt an evaluation. Diplopia suggests a mass, cerebral aneurysm, or elevated intracranial pressure (ICP).

Unfortunately, migraine headaches can produce an array of associated symptoms traditionally associated with secondary

</table>

headaches. Although nausea, vomiting, and photophobia can occur with increased ICP or infection, they are also associated with migraines. A helpful differentiating factor in migraineurs is whether these symptoms accompanied previous migraines or whether the finding is new. Visual abnormalities are associated with migraine headaches but also with idiopathic intracranial hypertension, temporal arteritis, and pituitary apoplexy.

**EXACERBATING AND ALLEVIATING FACTORS**

Determining exacerbating and alleviating factors is occasionally helpful. Post-LP headache tends to worsen on standing upright, and headache from sinusitis often worsens on bending forward with the head dependent. In contrast, the classic history of a headache caused by a brain tumor—worse on awakening—is neither specific nor sensitive because it is also seen in patients with hypercapnic chronic lung disease (in which the headache worsens during sleep). In terms of alleviating factors, diagnostic significance should not be ascribed to pain relief, even with over-the-counter medications.

**OTHER FACTORS**

Age is useful as a consideration because new-onset headache at older ages suggests a secondary cause such as giant cell arteritis, tumors, subdural hematoma, and side effects of medications. Environmental considerations include winter season and common-source clusters, which can indicate carbon monoxide poisoning.

**PAST AND FAMILY HISTORY**

Predisposing factors for a secondary cause of headache should be determined. For example, poorly treated hypertension may lead to hypertensive encephalopathy, vascular risk factors can result in stroke, and a past or family history of cerebral aneurysm increases the likelihood of subarachnoid hemorrhage (Box 101.1).

A history of thromboembolic events should raise the possibility of cerebral venous sinus thrombosis. In contrast,
patients with hemophilia are at higher risk for bleeding. Obesity suggests idiopathic intracranial hypertension (pseudotumor cerebri), especially in women. A history of cancer can raise suspicion for brain metastasis, and patients infected with human immunodeficiency virus or taking immunosuppressive medicines are at higher risk for infection.

**PHYSICAL EXAMINATION**

The physical examination (Box 101.2) is critical in guiding the differential diagnosis and appropriate work-up.

**GENERAL APPEARANCE AND VITAL SIGNS**

General appearance can be deceiving. For example, shielding one’s eyes from the light is seen with both migraine and meningitis. Fever is not a symptom of migraine and may suggest infection. A feverish patient with a headache and persistent hypertension may have an underlying mass lesion, and the absence of fever does not rule out meningitis or infection. A red eye with an edematous cornea and midposition pupil suggests narrow angle–closure glaucoma. A proptotic eye or chemosis is suggestive of cavernous sinus thrombosis. Papilledema is specific but poorly sensitive for increased ICP.

**HEAD AND NECK**

The head, eye, ear, nose, and throat examination may reveal the cause of the headache. Vesicles on the scalp, nose, or external ear canal suggest herpes zoster. Temporal artery tenderness, nodularity, or thickening suggests giant cell arteritis. A red eye with an edematous cornea and midposition pupil suggests narrow angle–closure glaucoma. A proptotic eye or chemosis is suggestive of cavernous sinus thrombosis. Papilledema is specific but poorly sensitive for increased ICP.

**NEUROLOGIC EXAMINATION**

Examination of the neck should be directed at signs of meningeval irritation. Meningismus (stiffness on passive flexion of the neck) may be seen in patients with infections (meningitis) or irritation (subarachnoid hemorrhage). However, this finding is not reliably present, and its absence does not exclude these diagnoses. One physical finding that is more reliable in diagnosing meningitis is “jolt accentuation”; when the patient is asked to turn the head quickly against resistance, there is a brief period of uncontrolled motion. This finding is seen in patients with posterior fossa lesions, such as a cerebellar hemorrhage or an acute stroke. The position of the neck can also be noted and compared to the opposite side. The skin of the neck should be checked for lesions such as vesicles, rash, or discoloration. The insertion of the temporalis muscle should be examined for tenderness, nodularity, or thickening, which can suggest giant cell arteritis.

**BOX 101.1 Critical Features of the History in the Emergency Department**

- **Timing**: Abrupt onset, “thunderclap” (pain rapidly reaches maximal intensity)
- **Location**: Nonspecific with regard to the differential diagnosis
- **Severity**: Worst of my life, most severe; have never been to an emergency department before for headache
- **Quality**: New type, qualitatively different from previous headaches
- **Associated Symptoms**: Fever, neck stiffness, Seizure, syncpe, Focal neurologic complaints, Visual abnormalities (diplopia, decreased or altered vision)
- **Exacerbating or Allieving Factors**: Worse with cough or lying down suggests increased intracranial pressure (but is not specific)
- **Past Medical History**: Stroke, vascular disease, cancer
- **Immunocompromised status**
- **Hypercoaguable states or bleeding diathesis**
- **Family History**: Hypercoaguable states, bleeding diathesis, cerebral aneurysm

**BOX 101.2 Critical Features (Potential Diagnoses) of the Physical Examination**

- **Vital Signs**: Fever (meningitis, encephalitis, abscess)
- **Elevated blood pressure (stroke or problems associated with elevated intracranial pressure)**
- **Head**: Vesicles on the scalp (herpes zoster of the upper two cervical roots or the root of the fifth trigeminal nerve)
- **Tender temporal artery (giant cell arteritis)**
- **Tender sinuses (sinusitis)**
- **Eyes**: Red, edematous (acute angle–closure glaucoma)
- **Proptosis (cavernous sinus thrombosis)**
- **Papilledema (increased intracranial pressure)**
- **Ears**: Vesicles in the external ear canal (Ramsay Hunt syndrome)
- **Nose**: Vesicles on the tip of the nose (herpes zoster of the root of the fifth trigeminal nerve)
- **Neck**: Meningismus with positive jolt accentuation, Kernig or Brudzinski sign (infection, subarachnoid hemorrhage)
- **Neurologic Examination**: Change in mental status (increased intracranial pressure, infection, carbon monoxide poisoning)
- **Decreased visual acuity (giant cell arteritis, acute angle–closure glaucoma)**
- **Visual field cut (mass lesion, pituitary apoplexy)**
- **Third nerve palsy (subarachnoid hemorrhage, cavernous sinus thrombosis)**
- **Sixth nerve palsy (increased or decreased intracranial pressure, basilar meningitis)**
- **Direction-changing nystagmus (cerebellar or brainstem stroke)**
- **Lower motor neuron seventh nerve palsy (Bell palsy, Ramsay Hunt syndrome)**
- **Eighth nerve palsy (diminished hearing or vertigo, Ramsay Hunt syndrome)**
- **Gait ataxia (cerebellar stroke)**
- **Any focal sensory or motor deficit (mass lesion, stroke)**
horizontally in alternate directions (as though rapidly shaking one’s head “no”) two to three times per second, the baseline headache increases in intensity.

**NEUROLOGIC EXAMINATION**

A complete neurologic examination of all patients with the chief complaint of headache should be performed and documented. Although some patients with migraine headaches may have neurologic deficits, the presence of new neurologic abnormalities should trigger a work-up beyond the history and physical examination. Abnormalities may suggest a diagnosis and the location of a mass lesion or cerebrovascular accident. Abnormal mental status with a new headache suggests increased ICP, a diffuse process such as meningitis, or carbon monoxide poisoning.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Following the history and physical examination, the EP must determine whether further diagnostic testing is necessary. Patients with new abnormal findings on physical examination clearly need further evaluation. Similarly, patients with a reassuring history and normal physical examination findings may require only appropriate analgesia and follow-up arrangements. Diagnostic dilemmas usually arise with patients who have normal findings on physical examination but some worrisome aspect of the history. No well-studied and validated decision rules have been published; for the most part, experience, judgment, and careful attention to the clinical examination and differential diagnosis guide further testing.

**COMPUTED TOMOGRAPHY**

Computed tomography (CT) is often the first neuroimaging test because it is both rapid and widely available. A non-contrast-enhanced CT scan is extremely sensitive for acute intraparenchymal bleeding and very sensitive for subarachnoid bleeding (Fig. 101.1), but small or less acute subarachnoid bleeding may not be visible. Although some small tumors and abscesses are not visible on a non–contrast-enhanced scan, some abnormal finding will usually be seen on such scans in patients with masses large enough to cause a significant headache or focal neurologic findings (Fig. 101.2). Any focal neurologic signs or symptoms should be conveyed to the radiologist reading the CT scan so that appropriate attention can be directed to the anatomic site in question.

Which patients require CT scanning is a matter of some debate. Hard and fast rules do not exist, but in general, high-risk factors indicate the need for CT (Box 101.3). The American College of Emergency Physicians has a clinical policy about the use of CT in some situations.

The type of CT to perform depends on the specific differential diagnosis under consideration. Imaging of a mass or an

**Fig. 101.2** Subdural hematoma.
abscess can be improved with intravenous infusion of a contrast agent. CT angiography (CTA) can be performed with multidetector scanners. Depending on the number of detectors, the software, and the skill of the neuroradiologist, CTA can approach conventional angiography in direct visualization of the cerebral vasculature. For patients in whom an arteriovenous malformation or aneurysm is suspected, CTA is a useful modality, although the standard diagnostic algorithm is still CT followed by LP.\textsuperscript{2-4} CT venography can be useful in the diagnosis of cerebral venous sinus thrombosis.

**MAGNETIC RESONANCE IMAGING**

In general, magnetic resonance imaging (MRI) is superior to CT, especially in evaluating vascular and neoplastic lesions and infections and pathology at the cervicomedullary junction and in the posterior fossa. Brain tumors, abscesses, ischemia, and pituitary apoplexy are easily visible. Recent studies suggest that MRI may even identify small cerebral hemor-

rhages that are not detected by CT scanning. Arterial and venous blood vessels can be evaluated by magnetic resonance angiography. Carotid and vertebral artery dissections, cerebral aneurysms, and cerebral venous sinus thrombosis can be diag-

nosed with magnetic resonance angiography and magnetic resonance venography.

Given the expense and scarcity of this resource, it is important that the EP carefully evaluate its necessity. For example, a headache patient with known thrombophilia or signs of cerebellar ischemia may require MRI evaluation for venous sinus thrombosis or a cerebellar stroke. Similarly, any newly documented neurologic deficit must be explained, and if contrast-enhanced CT scanning is not sufficient to find the cause, the EP should consider arranging for MRI, with the urgency depending on the clinical situation.

**LUMBAR PUNCTURE**

LP remains an important diagnostic tool for headache patients. In patients with subarachnoid hemorrhage, the EP must be aware that CT scanning may be nondiagnostic and that LP is the next step necessary.\textsuperscript{2}

LP can establish the diagnosis of suspected meningitis with nearly 100% sensitivity. Elevated opening pressure suggests idiopathic intracranial hypertension or cerebral venous sinus thrombosis. However, as with all tests in medicine, even LP has limitations. In particular, patients taking prednisone, who are otherwise immunocompromised, may not have the elevated cerebrospinal fluid white blood cell count expected. LP to rule out subarachnoid hemorrhage can be traumatic as well, thus making interpretation difficult. In such cases, an elevated opening pressure may help identify pathology such as subarachnoid hemorrhage.

**LABORATORY STUDIES**

Routine laboratory studies are rarely helpful and not recommended in the work-up of patients with headache. In a few very specific circumstances, targeted laboratory tests can be helpful. Such tests include an erythrocyte sedimentation rate if giant cell arteritis is suspected, a toxicology screen for cocaine or other sympathomimetics in cases of intracranial hemorrhage in which they might play a role, and a carboxyhemoglobin level in patients with suspected carbon monoxide poisoning.

**TONOMETRY**

Tonometry is a critical test in the ED for patients with headache, eye complaints, and findings that suggest acute narrow angle–closure glaucoma.

**TEMPORAL ARTERY BIOPSY**

Temporal artery biopsy helps diagnose giant cell arteritis. When this diagnosis is suspected, high-dose oral steroid therapy should be started and arrangements made for the patient to see a surgeon for biopsy within the next week or so.

**NEUROLOGY CONSULTATION**

One final issue to be considered is neurology consultation. The timing of consultation can vary, depending on the differential diagnosis and the duration of the headache. In patients with a new, definite neurologic finding on physical examination and normal results on brain imaging, the physician should consider neurologic consultation on an urgent or emergency basis.

**TREATMENT**

Airway protection is always paramount in a critically ill patient. Patients with impending herniation from a mass lesion or intracranial bleeding may require intubation. Although neurologic examination is important in the acute phase of the patient's hospitalization, short-term paralysis for rapid-sequence intubation can and should be used to achieve the optimal intubation conditions. Lidocaine and fentanyl are sometimes advocated to blunt the transient rise in ICP that accompanies tracheal intubation. If feasible, a quick neurologi-

cal examination should be performed first.

Once the airway is secure, sedation should be adequate (to avoid elevations in ICP), but oversedation should be avoided to provide the best possible serial neurologic examination (propofol is a short-acting sedative that is useful for this purpose). If airway management precedes imaging, emergency neuroimaging should rapidly follow intubation.

For patients with signs or symptoms of acute bacterial meningitis, a critical early decision is whether to perform a CT scan or proceed directly to LP (Box 101.4). Administration of antibiotics should not be delayed in patients who have signs of acute meningitis. Performing LP directly in an alert, neurologically intact patient with no medical history is usually safe, especially in those with normal venous pulsations on funduscopéy.

**PRIORITY ACTIONS**

Treat pain early and adequately. The response to pain should not affect the work-up, so there is no reason to withhold appropriate analgesia.

Patients with hemophilia and headache require coagulation factor repletion on an emergency basis, sometimes even before head computed tomography, given their high risk for intracranial hemorrhage.

Patients with signs and symptoms of acute bacterial meningitis require early antibiotics, even if the diagnosis is not yet established.
Hypertensive Encephalopathy
Reduction of mean arterial pressure (MAP) by 25% should improve the headache and other signs of end-organ damage.

Ruptured Cerebral Aneurysm
Although high-quality evidence is lacking, it is generally considered prudent to lower systolic BP to less than 140 or even 120 mm Hg with labetalol, nitroprusside, or nicardipine. This is in contrast to an ischemic stroke, in which higher BP levels (up to 220/120 mm Hg) are acceptable or even desired.

Intraparenchymal Hemorrhage
Data to guide BP management in patients with intraparenchymal hemorrhage are limited, and no trial has demonstrated improved outcomes with reduction in BP. The American Heart Association published updated guidelines in 2010. There has been a trend away from nitroprusside and toward nicardipine and labetalol.

The 2010 guidelines state the following:

1. If systolic BP is higher than 200 mm Hg (MAP > 150), aggressive reduction with continuous intravenous medication and monitoring of BP every 5 minutes should be considered.
2. If systolic BP is higher than 180 mm Hg (MAP > 130) AND ICP is possibly increased, monitoring ICP and reducing BP to maintain cerebral perfusion pressure higher than 60 should be considered.
3. In patients with a systolic BP of 150 to 220 mm Hg, acute lowering to 140 systolic is “probably safe.”

GIANT CELL ARTERITIS (TEMPORAL ARTERITIS)
Giant cell arteritis is classically manifested as a sudden, severe temporal headache in patients older than 50 years. A major differentiating feature of this disease is the presence of ischemic symptoms such as jaw claudication, scalp tenderness, or visual loss. In the ED, giant cell arteritis is a clinical presumptive diagnosis; therefore, high-dose prednisone should be administered empirically immediately. Temporal artery biopsy should be scheduled within a week or so to establish a definitive diagnosis, although even a negative biopsy result does not definitively exclude this disorder. The decision whether to continue steroid therapy following negative biopsy findings should be made by the primary care physician in consultation with appropriate specialists.

ACUTE ANGLE-CLOSURE GLAUCOMA
Patients with acute angle-closure glaucoma typically have a recurrent unilateral headache behind the eye associated with blurred vision and erythema; there will often be a prolonged course of symptoms before appropriate diagnosis. Although the diagnosis is usually based on clinical findings, tonometry can establish the condition. Intraocular pressure in the affected eye will be elevated up to 40 to 80 mm Hg. In addition to appropriate pain control, any or all of the following therapies may be considered:

1. Acetazolamide, 500 mg intravenously followed by 500 mg orally
2. Timolol, 0.25% to 0.5% applied topically
3. Prednisolone, 1 to 2 drops onto the affected eye
4. Pilocarpine, 2% applied topically
5. Isoosorbide, 1 to 2 drops onto the affected eye
6. Mannitol, 1.5 g/kg orally, or glycerin, 1 to 2 g/kg orally
7. Antiemetics and analgesia as needed
8. Anterior chamber paracentesis

An ophthalmologist should be consulted on an emergency basis for definitive peripheral iridectomy or laser iridotomy.

SINUSITIS-RELATED HEADACHE
A diagnosis of sinus-related headache should be made with caution because paranasal sinus mucosal thickening is a common incidental finding on CT and does not imply causality. Pain control is the cornerstone of treatment. Nonsteroidal agents and decongestants can be provided. Oxymetazoline nasal spray should be used for no more than several days. The Centers for Disease Control and Prevention recommends that the diagnosis of bacterial sinusitis be made only after 7 days of symptoms and that amoxicillin should be a first-line agent for mild sinusitis in patients with no previous antibiotic use.

MIGRAINE HEADACHE
Migraine headache is classically defined as a throbbing unilateral headache with associated symptoms, including photophobia, phonophobia, nausea, and vomiting. The headache can be preceded by an aura, such as scintillating scotomata, jagged lines, or other visual abnormalities. Neurologic signs, including hemiparesis, paresthesias, ophthalmoplegia, and aphasia, can complicate migraine. Patients will usually have a history of similar headaches and frequently a family history of migraines.

Migraine is most confidently diagnosed by a history of at least five similar headaches with several specific criteria. New-onset headaches or those of a different or unusual quality often require further work-up. One cannot definitively
**SECTION IX ▪ NERVOUS SYSTEM DISORDERS**

### BOX 101.5 Management of Moderate to Severe Acute Migraine Headaches

- **Analgesics (first-line agents)—use in combination with antiemetics**
  - Aspirin, 81-325 mg
  - Acetaminophen, 325-1000 mg
  - Paracetamol—available outside the United States
- **Sumatriptan, 6 mg SC—orally available as a nasal spray**
- **Dihydroergotamine, 0.5-1 mg IV—may be second line with respect to triptans or antiemetics**
- **Ergotamine**
- **Steroids—no clear benefit acutely but may decrease recurrence**
  - Dexamethasone, 10 mg IV

### BOX 101.6 Acute Management of Cluster Headache

- **Oxygen, 7 L/min for 15 minutes by face mask**
- **Sumatriptan, 6 mg subcutaneously or 20 mg by nasal spray**

**Dihydroergotamine nasal spray (Note: Do not combine ergotamines with sumatriptan)**

- **Lidocaine intranasally, 1 mL of a 4% solution ipsilaterally**

### BOX 101.7 Acute Management of Tension Headache

- **Nonsteroidal antiinflammatory drugs**
- **Antihistamines**
  - Diphenhydramine (Benadryl)
  - Promethazine (Phenergan)
- **Antiemetics**
  - Metoclopramide (Reglan)
  - Prochlorperazine (Compazine)
- **Butalbital-containing agents**
  - Acetaminophen + caffeine + butalbital
  - Aspirin + caffeine + butalbital

**TENSION HEADACHE**

Tension headache is usually characterized by throbbing pain that radiates bilaterally from front to back and to the neck muscles. As with migraine headaches, one cannot firmly diagnose tension headache after a single episode, and this diagnosis requires more than nine previous episodes. Pain control consists of nonsteroidal antiinflammatory drugs, antiemetics, and perhaps caffeine (Box 101.7). Butalbital-containing agents (as with migraine headaches) may be used with caution, given the risk for dependency and rebound headache.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Disposition is entirely a function of the cause of the headache and the need for further treatment or, in some cases, pain control.

**DOCUMENTATION**

The history in every headache patient should include the onset, timing, severity, comparison with previous headaches, and any new neurologic complaints.

The physical examination should include a complete neurologic and head, eye, ear, nose, and throat examination. Any new neurologic findings must be explained.

Visual fields and gait assessment cover a wide range of neuroanatomic territory and are often either inadequately tested or inadequately documented.

Be very careful assigning the diagnosis of migraine headache to patients if they do not already have this diagnosis or if the current headache is different from their usual migraines.

diagnose migraine or tension headache at the initial onset of a new headache.

**Box 101.5** summarizes the various agents that are useful in the management of acute migraine. Although opiates are used frequently in the ED, they should not be first-line treatment and should be reserved for rescue therapy in patients who do not respond to the initial medications—and even in this situation they should be used sparingly.

**CLUSTER HEADACHE**

Cluster headache is typically a severe unilateral headache that can be accompanied by conjunctival injection, lacrimation, ptosis, miosis, rhinorrhea, and nasal congestion. Attacks can occur up to eight times a day and are severe but short-lived; the autonomic symptoms are typically unilateral and ipsilateral to the pain. Recognition is important because this headache subtype is uniquely sensitive to oxygen. Mainstays of emergency management include administration of oxygen and subcutaneous sumatriptan (Box 101.6).
Complications and Pitfalls
Just because a patient states that he or she has had “migraine” (or “tension” or “sinus”) headaches does not mean that the headaches ever formally met these criteria or have ever been evaluated or that this headache is the same as the previous headaches. This is especially true for recent-onset headaches.
If head computed tomography is performed to evaluate for subarachnoid hemorrhage, it should always be followed by lumbar puncture to evaluate for xanthochromia and the presence of blood.
Visualization of mucosal thickening in the paranasal sinuses on computed tomography is a common incidental finding and should not be used to diagnose acute sinusitis.
A favorable response to analgesics has little or no diagnostic significance and should not be used to exclude a secondary cause of headache.

Intracranial and Other Central Nervous System Lesions

Steven M. Zahn

102

KEY POINTS

- A comprehensive patient history is imperative to narrow the differential diagnosis when a new mass lesion is discovered on radiographic imaging.
- A complaint of dizziness requires cerebellar testing, including finger-nose, heel-shin, dysdiadochokinesia, and gait evaluation.
- Fever in the setting of a neurologic complaint requires both a neurologic examination and consideration of neuroimaging.
- Any patient with a first-time seizure warrants a non-contrast-enhanced computed tomography (CT) scan of the head regardless of age (Box 102.1).
- CT scans reliably demonstrate lesions 1.0 cm or larger.
- Magnetic resonance imaging should be performed if there is significant concern for a central nervous system lesion in patients with negative CT findings.

EPIDEMIOLOGY

Patients with intracranial lesions typically have headaches, seizures, focal neurologic changes, weakness, fatigue, or any combination of these findings. Headaches occur in approximately 50% of patients with central nervous system (CNS) tumors; however, brain tumors are uncommon in patients with a headache and normal findings on neurologic examination (<1% of the time). Thus emergency physicians should always consider the presence of a brain tumor in the differential diagnosis but should use neuroimaging judiciously (Table 102.1). Focal neurologic changes always warrant further investigation, including laboratory tests, radiographic imaging, and neurologic or neurosurgical consultation (or both).

PATHOPHYSIOLOGY

Small intracranial lesions can drastically affect important neural pathways within the CNS. Frequently, a non-CNS malignancy is first identified by a neurologic manifestation of a metastatic lesion. Lesions located near or within the ventricular system can be manifested as changes in intracranial pressure (ICP) and thus affect the clinical findings. However, slow-growing lesions of a primary CNS origin located in clinically silent regions of the brain such as the frontal lobe may be present for years before detection.

Autopsy diagnosis reveals that nearly 25% of patients who die of cancer had intracranial metastasis (Fig. 102.1). The lung is the most common origin of brain metastases. Breast cancer (especially ductal carcinoma) has a propensity to metastasize to the cerebellum and the posterior pituitary gland; however, breast cancer that metastasizes to bone tends to not metastasize to the brain.

Other common origins of brain metastases are gastrointestinal malignancies (most commonly colon and rectum), renal carcinoma, and melanoma. In contrast, prostate, esophageal, and ovarian cancer and Hodgkin disease rarely metastasize to the brain.

Although metastatic disease is a common form of intracranial mass lesion, other mass lesion considerations include lymphoma (Fig. 102.2), glioblastoma multiforme (Fig. 102.3), astrocytoma, ependymoma, meningioma, oligodendroglioma, and others.

**Fig. 102.1** Axial magnetic resonance image demonstrating a metastatic lesion present at the gray-white matter junction with significant surrounding edema. The hyperdense focus within the lesion probably represents calcification or blood.

**Fig. 102.2** This computed tomography scan demonstrates the classic periventricular homogeneous lesion of a central nervous system lymphoma; it has a ring-enhancing appearance when viewed with contrast enhancement.
nervous system disorders

**Fig. 102.3** The lesion in this computed tomography scan illustrates the characteristic features of glioblastoma multiforme: heterogeneous irregular ring of enhancement, hypointense core, and significant surrounding edema.

medulloblastoma, hemangioblastoma, neurocysticercosis, toxoplasmosis, tuberculoma, tuberous sclerosis, and arteriovenous malformations.

**PRESENTING SIGNS AND SYMPTOMS**

CNS mass lesions are usually manifested as one of three syndromes: (1) subacute progression of a focal neurologic deficit; (2) seizure; or (3) a nonfocal neurologic disorder such as headache (especially with nocturnal features or occurrence on awakening), dementia, changes in personality, or gait disorder. The presence of systemic symptoms (malaise, fever, weight loss) suggests a metastatic rather than a primary brain tumor or an infectious process such as toxoplasmosis or tuberculoma.

The initial complaint related to a CNS lesion may be attributable to an increase in ICP. Nausea, vomiting, lethargy, and morning headaches are common symptoms that are mistaken for other organ system involvement but are classic findings in patients demonstrating a rise in ICP. Hydrocephalus arising from a strategic location of a CNS lesion can lead to dizziness, ataxia, and vomiting as a result of obstruction to flow of cerebrospinal fluid.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The initial diagnostic modality in a patient with a new neurologic complaint is a non–contrast-enhanced computed tomography (CT) scan. Most brain tumors causing clinical symptoms are visible on CT scans, and all are visible with the various contrast-enhanced techniques of CT and magnetic resonance imaging (MRI). On nonenhanced CT, brain tumors are visualized by mass effect and altered attenuation. Masses may be hypodense, isodense, or hyperdense with respect to surrounding structures and can be associated with vasogenic edema, which is visualized by low attenuation of the white matter (Box 102.2). Extraaxial lesions can best be appreciated with bone window settings because bone erosion or hyperostosis may be present.

Calcification can be useful in isolating brain tumors. Oligodendroglialomas contain calcification in 90% of cases. Other tumors with calcification include choroid plexus tumors, ependymoma, central neurocytoma, meningioma (Fig. 102.4), craniopharyngioma, teratoma, and chordoma. Nonmalignant lesions such as neurocysticercosis, toxoplasmosis, and tuberous sclerosis exhibit calcific changes on radiographic imaging as well (Table 102.2).

Ring enhancement on contrast-enhanced imaging modalities may expand the differential diagnosis to toxoplasmosis, neurocysticercosis, or even multiple sclerosis. Multiple lesions in various stages of development are characteristic of neurocysticercosis. Multiple sclerosis is a common misdiagnosis in the setting of primary CNS lymphoma because both have features of white matter lesions on MRI.

Hemorrhage within a defined lesion on a CT scan should suggest the possibility of an arteriovenous malformation or hemangioblastoma (Fig. 102.5). Contrast-enhanced CT or MRI may identify more than 95% of arteriovenous malformations. Lesions appear as a heterogeneous, hypodense mass

Infections

- Abscess
- Toxoplasmosis
- Neurocysticercosis
- Tuberculoma
- Progressive multifocal leukoencephalopathy

Vascular disease

- Hemorrhage
  - Anomalies (arteriovenous malformation)
  - Intratumoral
  - Hypertensive

Infarct

- Embolism
- Thrombosis (sinus venous)

Inflammatory

- Multiple sclerosis
- Encephalomyelitis
The meningioma seen on this computed tomography scan has the classic extraaxial appearance of this lesion. Meningiomas are often hyperdense and may demonstrate calcification.

Constitutional symptoms should be accounted for when interpreting CNS lesions on radiographic images. Fever or laboratory findings such as leukocytosis or an unusual differential feature (elevated lymphocyte or eosinophil count) may raise suspicion for an infectious cause such as tuberculoma or toxoplasmosis instead of a primary brain tumor or a metastatic lesion.

**TREATMENT**

Prehospital evaluation for possible intracranial lesions involves basic emergency medicine principles for airway support and monitoring of breathing. Seizure may be a manifestation that should require standard antiepileptics and airway management. Mass lesions near the pons and medulla, as well as those leading to hemorrhage and a mass effect, will require emergency airway support.

A variety of treatment options are available for the myriad of intracranial lesions possible. Most, if not all modalities should
be performed in consultation with neurology and neurosurgery. The majority of lesions require additional specialized diagnostic testing such as serologic analysis and biopsy, which makes the final diagnosis a responsibility of the consultants.

Primary and metastatic brain lesions may require a multifaceted approach to medical care. In the emergency department setting, glucocorticoids and prophylactic antiepileptics (phenytoin, fosphenytoin, phenobarbital) may be given before admission. Surgery, radiation therapy, and chemotherapy are options for further long-term treatment plans, but they are usually tailored to the specific tissue diagnosis when it pertains to a solid mass lesion.

Infectious lesions such as abscesses (Fig. 102.7), neurocysticercosis, toxoplasmosis, and tuberculomas usually require consultation with infectious disease specialists. Serologic examination may prove useful for determining a diagnosis and treatment approach. Antibiotic and antiparasitic medications may be administered under the guidance of these consultants; regimens including clindamycin, albendazole, praziquantel, sulfadiazine, and pyrimethamine may be instituted with or without glucocorticoids.

Special situations include hemorrhaging lesions, such as metastatic lesions or arteriovenous malformations, which may necessitate the use of coagulation factors such as fresh frozen plasma, platelets, or factor VII given the location, mass effect, and patient-specific comorbid conditions.

### FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Most lesions that are discovered on CT or are due to a neurologic abnormality require further inpatient diagnosis and treatment as stated in the previous section. Patients with
meningiomas or those with a known diagnosis of a chronic condition such as tuberous sclerosis may be discharged and close follow-up with primary and specialty physicians arranged. Any new lesion (except for a solitary meningioma, for example) or signs of a mass effect require emergency consultation with a specialty service.

REFERENCES

Intracranial hemorrhages have different clinical manifestations ranging from subtle to catastrophic. The efforts of the emergency physician (EP) are directed toward identifying the correct diagnosis, confirming the diagnosis by cranial computed tomography (CT) or other diagnostic tests, and providing supportive care. Liberal consultation plus collaboration with specialists is required. Strong evidence of the best course of action regarding basic treatment issues such as blood pressure management and the use of anticonvulsants is lacking. Definitive therapy is most often in the hands of consulting and admitting physicians.

It is tempting to place any intracranial hemorrhage in the diagnostic category head bleed. Different types of intracranial hemorrhage may have different causes, different natural histories, different diagnostic strategies, different treatments, and frequently different prognoses. It is important to delineate the various types of intracranial hemorrhage so that correct diagnostic steps and therapeutic interventions can be performed.

Epidemiology

Estimates of the incidence of intracranial hemorrhage in patients seen in the emergency department (ED) are difficult because the findings include isolated headache, stroke syndromes, and head trauma, but a few generalities may be made.

Pathophysiology

Intracranial hemorrhage is the umbrella term used to encompass the many types of bleeding within the cranial vault (Figs. 103.1 to 103.5 and Table 103.1). Intraparenchymal hemorrhage implies blood within the substance of the brain. When the hemorrhage is not clearly secondary to a detectable cause, it is deemed a spontaneous hemorrhage. This term is often used synonymously with the terms hypertensive hemorrhage and, when anatomically appropriate, intracerebral hemorrhage. Intraparenchymal hemorrhages may also occur in the brainstem or cerebellum. SAH literally describes blood in the subarachnoid space, and if nontraumatic, a vascular lesion such as an aneurysm is the implied cause of the bleeding. SAH and intraparenchymal hemorrhage may coexist. Intraventricular hemorrhage means that blood is visualized within the ventricles by cranial CT, and it is most often present with other types of intracranial hemorrhage. Intracranial hemorrhages outside the brain substance are referred to as extraaxial hemorrhages and include both subdural hemorrhages and epidural hemorrhages. Although uncommon exceptions exist, extraaxial hemorrhages almost always have a traumatic etiology. The term hemorrhagic stroke might literally describe abrupt symptoms with any of the previously mentioned hemorrhages, but it is sometimes used in a more restrictive sense to describe hemorrhagic changes in an area of ischemic stroke to the point of being visible on cranial CT; this is termed hemorrhagic transformation of ischemic stroke.

</table>
Intracranial bleeding may be of either arterial or venous origin. Because of the closed nature of the cranial vault, any increase in intracranial volume from bleeding may result in increased intracranial pressure (ICP) and decreased cerebral perfusion pressure (CPP). As a mass expands, some initial compensation occurs in the form of diminished intracranial vascular and cerebrospinal fluid volume. However, at some point the compensatory mechanisms fail and ICP will dramatically rise with a further increase in size of the mass. A key concept is CPP, the effective blood pressure exerted on the intracranial contents. CPP is equal to mean arterial pressure (MAP) minus ICP:

\[
CPP = MAP - ICP
\]

If ICP increases abruptly or if MAP falls, CPP decreases and central nervous system ischemia may follow and exacerbate the neuronal injury.

Hemorrhages also cause injury by direct tissue destruction or compression of adjacent structures. Edema formation around a hematoma may further increase the mass effect. For example, with cerebellar hemorrhages, tissue damage may cause the initial symptoms, but increased ICP and rapid progression to coma result from compression of the adjacent brainstem.

Spontaneous intraparenchymal hemorrhages (e.g., intracerebral hemorrhages, lobar hemorrhages, hypertensive hemorrhages) are most often associated with chronic hypertension. Cerebral amyloid angiopathy is increasingly being recognized...
Common sites and sources of intracerebral hemorrhage. Intracerebral hemorrhages most commonly involve the cerebral lobes, with origin from penetrating cortical branches of the anterior, middle, or posterior cerebral arteries (A); the basal ganglia, with origin from ascending lenticulostriate branches of the middle cerebral artery (B); the thalamus, with origin from ascending thalamogeniculate branches of the posterior cerebral artery (C); the pons, with origin from paramedian branches of the basilar artery (D); and the cerebellum, with origin from penetrating branches of the posterior inferior, anterior inferior, or superior cerebellar arteries (E).

as a contributing process in the elderly. Chronic excessive alcohol use is also a risk factor. Hemorrhage usually originates from rupture of small penetrating branch arteries of the vessels at the base of the brain¹ (Fig. 103.6).

Serial cranial CT demonstrates that many intracerebral hemorrhages expand over the course of several hours.² The initial hemorrhage may infiltrate the white matter with little direct destruction, but continued hematoma expansion, white matter edema, additional hemorrhage from surrounding vessels, and the development of hydrocephalus may all contribute to increased ICP and secondary neuronal injury. The frequency of anticoagulant-associated intracerebral hemorrhage is increasing.³ Warfarin therapy does not appear to increase hematoma volume initially, but it does increase the risk for later hematoma expansion.⁴

SAH literally means “blood in the subarachnoid space.” Trauma is the most common cause. Spontaneous, or nontraumatic, SAH has an entirely different differential diagnosis. About 80% of spontaneous SAHs are caused by rupture of saccular (berry) aneurysms of the intracranial vessels, which are commonly located near intracranial arterial bifurcations of the circle of Willis⁵⁻⁶ (Fig. 103.7). Aneurysms are often named after the vascular site of origin, such as the anterior communicating artery or middle cerebral artery. Aneurysms that develop following vascular infection from endocarditis are termed mycotic aneurysms. Some aneurysms also cause symptoms without rupture from a mass effect or from emboli originating within the aneurysm. Rupture of an intracranial aneurysm abruptly raises ICP and leads to the onset of symptoms. The bleeding may be confined to the subarachnoid space, or a hematoma may extend into the brain substance and create an intraparenchymal hemorrhage, which in turn may rupture into the ventricles. Vasospasm of the vascular tree related to the aneurysm typically takes hours to develop and may worsen regional ischemia.

Arteriovenous malformations are another cause of intracerebral hemorrhage of both the subarachnoid and intraparenchymal anatomic subtypes. These arteriovenous shunts vary in their anatomy, and many patients have saccular aneurysms as well. Lesions with deep venous drainage and high pressure in the feeding vessels are at increased risk for bleeding.⁷ Cavernous angiomas are low-pressure vascular lesions associated with small hemorrhages.

Closed head injury may cause diffuse or localized subarachnoid bleeding. Cerebral contusion is a loosely defined term that describes the CT appearance of low density consistent with edema and often with some hemorrhage within that region.

An epidural hematoma usually reflects arterial bleeding into the epidural space following injury to a meningeal artery. A common mechanism is a skull fracture in the temporal area with associated laceration of the middle meningeal artery. The arterial pressure hematoma may increase in size until tamponade occurs as a result of resistance of distorted intracranial structures and increased ICP (at the expense of CPP).

Subdural hematomas reflect bleeding from small vessel sources and from diffuse brain injury with hemorrhage accumulating over the surface of the brain. Again, distortion of the cranial contents may occur, as well as increased ICP. The cortical atrophy that occurs with aging is thought to make the bridging vessels from the cortex to the dura increasingly susceptible to rupture from even trivial trauma in the elderly.

Less common causes of intracranial hemorrhage include dural sinus thrombosis with venous infarction and
Intracranial hemorrhages of any type may be associated with a continuum of changes in mental status ranging from mild headache to agitation, confusion, and coma. Seizures and stroke symptoms are also common findings.

Patients with a large intracranial hemorrhage typically have a diminished level of consciousness with or without a focal neurologic deficit. Intracerebral hemorrhages are responsible for about 20% of acute strokes. It is not possible at the bedside to reliably distinguish between an ischemic stroke and an intracerebral hemorrhage. Patients with a diminished level of consciousness often have a larger hemorrhage and increased ICP or distortion of the thalamic and brainstem reticular activating system.1

With increased ICP, the Cushing triad of hypertension, bradycardia, and irregular respirations may be present, but this is not specific for intracranial hemorrhage. If able to speak, many patients complain of headache and nausea. Depending on the region of brain injured, the examiner will often find corresponding neurologic deficits. With hemispheric lesions, the picture may be similar to ischemic stroke—that is, patients with a large left cerebral hemorrhage may have right-sided hemiparesis and aphasia. Other stroke syndromes of neglect, visual field defects, and cortical sensory abnormalities may be present. With frontal lesions, conjugate eye deviation toward the side of the lesion is common. Large hematomas with mass effects may present the clinical picture of uncal herniation with diminished consciousness and third nerve dysfunction.
An axial section of a non–contrast-enhanced computed tomography scan of the head reveals four types of acute posttraumatic intracranial hemorrhage: an epidural hematoma (thin white arrow) on the left side, a laminated subdural hematoma (short black arrow) on the right side, right-sided periventricular and frontal lobe contusions containing an intraparenchymal hematoma (thick white arrow), and a subarachnoid hemorrhage (long black arrow) in the right frontal region.

An expanding unruptured aneurysm may be accompanied by cranial nerve abnormalities. Typically, this is a third nerve paresis with asymmetric pupils and impairment of extraocular movement. The pupillary reflex may or may not be impaired.

With SAH and increased ICP, cardiac arrhythmias and changes on the electrocardiogram (ECG) consistent with myocardial ischemia may at times confound the diagnosis. Usually, these patients have severe neurologic symptoms, but cases in which the arrhythmia overshadows the clinical findings are reported as well.

Intracerebral hemorrhage is the most common manifestation of arteriovenous malformations and accounts for roughly half the presentations. Other manifestations include seizures and focal neurologic deficits.

A history of trauma suggests the possibility of an extraaxial hematoma. Progression of symptoms or deterioration in level of consciousness mandates investigation for an expanding mass lesion. With epidual hematoma, the classic description (present in only a minority of patients) is a transient loss of consciousness followed by an alert or lucid interval and later by progressively decreased level of consciousness. Headache out of proportion to the head blow or the presence of persistent vegetative symptoms such as nausea and vomiting is the more common manifestation. As the mass progresses, the neurologic findings may progress. Altered mental status following trauma is the typical clinical scenario.

Chronic large subdural hematomas may be found during evaluation of patients for altered mental status or headaches. Occult manifestations of intracranial injury are more common in the elderly.

### Differential Diagnosis and Medical Decision Making

The major differential diagnosis of intracranial hemorrhage with focal neurologic signs or symptoms is ischemic stroke. Both processes may be associated with an abrupt onset of symptoms and focal neurologic deficits. Intracranial neoplasms are also in the differential diagnosis. However, the spectrum of findings in patients with intracranial hemorrhage is wide. Seizures are not a frequent initial complaint of patients with intracranial hemorrhage, although they do occur with enough frequency to include intracerebral hemorrhage and SAH in the differential diagnosis of seizures. Abnormal decerebrate posturing, which may occur with intracranial hemorrhage, is sometimes mistaken as seizure activity, particularly if it is brief and repetitive. Though counterintuitive, infectious processes such as encephalitis and meningitis may at times also have an abrupt onset of symptoms.

If altered mental status is the initial finding, all the causes of altered mental status should be included in the differential
The existence of an isodense hematoma must be inferred from cortical sulcus markings that do not reach the cranium. Clinically, the terms acute, subacute, and chronic are used to reflect the change in appearance on the CT scan, from hyperdense to isodense and finally hypodense. Nonhomogeneous density may be observed in some cases and is an indication of acute or acute on chronic bleeding. The possibility of hyperacute bleeding should always be kept in mind, with the areas of rapid bleeding appearing relatively hypodense within a larger, more dense area on CT.

**QUESTION 2—WHERE IS THE HEMORRHAGE?**

If hemorrhage is present, it is then described as external to the brain substance (extraaxial), within the substance of the brain (intraaxial or intraparenchymal), or visible in the intraventricular and subarachnoid or cisternal spaces. Extraaxial hematomas have two basic types of appearance. Subdural hematomas are most often crescentic (see Fig. 103.3), whereas epidural hematomas have a typical lens-shaped pattern (see Fig. 103.4). An intraparenchymal hemorrhage may be located in the cerebrum (intracerebral hemorrhage) or in subcortical or brainstem structures. Intracerebral hematomas of hypertensive origin tend to be situated in deep white matter or the basal ganglia or are confined to one lobe of the brain (lobar) (see Fig. 103.1). These hemorrhages tend to have a stereotypic pattern, and deviation from these patterns may suggest an uncommon cause of the hemorrhage.

Cerebellar hemorrhages may be midline or hemispheric (Fig. 103.12) and may cause brainstem compression. SAH may be detected by high density in the suprasellar or perimesencephalic cistern or by blood in the cortical sulci, where ordinarily there should be low-density images from the cerebrospinal fluid signal. Depending on the degree of hemorrhage, SAH may be obvious (Fig. 103.13) or relatively subtle (see Fig. 103.2). Intraventricular hemorrhage (literally “blood within the ventricles”) may result from rupture of an intracerebral hemorrhage into the ventricular system, from trauma, or from SAH (Fig. 103.14).
**QUESTION 3—HOW MUCH BLOOD IS PRESENT, AND WHAT IS THE EFFECT?**

Some quantification of the hemorrhage should follow. For extraaxial hemorrhage, the greatest thickness of the hematoma is easily estimated from the ruler on the CT scan. Volumetric estimation of intraparenchymal hematomas may be estimated from information present on the cranial CT scan, although this is not usually done frequently by EPs. Because most hemorrhages are ellipsoid, the formula $ABC/2$ may be used to estimate the volume, where $A$ is the greatest hemorrhage diameter on CT, $B$ is the diameter 90 degrees to $A$, and $C$ is the approximate number of CT slices with hemorrhage multiplied by slice thickness. Of more importance is any effect that the hematoma is having on adjacent structures. This may be estimated qualitatively by noting any compression on the ventricular system and the amount of shift of midline structure, as well as by CT signs of herniation (subfalcine, uncal, tonsillar herniations).

**QUESTION 4—WHAT IS CAUSING THE BLEEDING?**

Some cranial CT scan patterns of intracranial hemorrhage are sufficiently typical that an etiologic diagnosis may be suspected. For example, in a middle-aged or elderly patient with a spontaneous intracerebral hemorrhage in the deep white matter, the term *hypertensive hemorrhage* may be used. The same hemorrhage in a much younger patient might suggest a vascular lesion such as an arteriovenous malformation as the cause. One must remember that the specific cause of a hemorrhage seen on a CT scan is garnered from pattern recognition and is speculative to some degree.

Conventional angiography with selective injection of contrast material has traditionally been used when vascular lesions such as aneurysms or arteriovenous malformations are suspected. CT angiography with intravenously administered radiographic contrast material is increasingly being used instead of conventional angiography. Selection of direct vascular imaging is determined by a radiologist, neurologist, or neurosurgeon. (Discussion of this modality is outside the scope of this chapter.)

The role of magnetic resonance imaging (MRI) in current emergency medicine practice is evolving. In some centers, magnetic resonance angiography or venography is used, although again this is done in consultation with the admitting physicians or services. The traditional view is that MRI is inferior to CT when acute intracranial hemorrhage is suspected; however, recent literature suggests that with some technical adaptations, MRI may readily detect hemorrhages.

Lumbar puncture can increase the sensitivity for the detection of SAH in patients with negative or equivocal results on CT scanning. The common procedure is to collect cerebrospinal fluid in four tubes and obtain a cell count in tubes 1 and 4. Findings consistent with SAH include the presence of xanthochromia and a red blood cell count that does not diminish.
from tube 1 to tube 4. Xanthochromia from the breakdown of red blood cells may take more than 12 hours to develop and may not be present when lumbar puncture is performed soon after the onset of symptoms. The most common method of determining xanthochromia in the clinical laboratory is visual inspection, although some studies show that spectrophotometry is superior. Lumbar puncture performed to exclude SAH sometimes reveals unexpected diagnoses such as meningitis. Basic laboratory work should include coagulation studies and platelet counts if hemorrhage is suspected.

**TREATMENT**

Supportive care including appropriate management of the ABCs—airway, breathing, and circulation—is of course important. The decision to perform endotracheal intubation is based on the judgment of the physician who assesses the patient’s ability to protect the airway. It is recommended that certain steps be taken for rapid-sequence induction in patients with intracranial hemorrhage or other conditions with suspected increased ICP, including the use of lidocaine and a defasciculating dose of a paralytic agent, although rigorous proof of efficacy is lacking. In the past, hyperventilation was recommended with the goal of reducing abnormally increased ICP. Again, evidence is lacking, but the consensus is that hyperventilation beyond that needed to reduce PaCO₂ to only a small degree (PaCO₂ of 30 to 35 mm Hg) is not indicated.15

Blood pressure management in the setting of intracranial hemorrhage is controversial. In multiple-trauma patients with central nervous system injury, hypotension is associated with a poor outcome. In patients with intracerebral hemorrhage, the risk of expanding a hematoma associated with sustained hypertension must be weighed against the risk of impairing cerebral perfusion if blood pressure is reduced. A 2010 study suggested a trend toward more favorable outcomes in patients with aggressive blood pressure reduction but admitted that the study was underpowered and called for further investigation.16

In patients with established intracerebral hematoma and hypertension, consensus at this time is to use intravenous agents that can be titrated, such as nitroprusside, labetalol, esmolol, or carvedilol, if needed, to maintain blood pressure with an MAP of less than 130 mm Hg. Systolic blood pressure greater than 180 mm Hg or diastolic blood pressure higher than 105 mm Hg on two readings taken 5 minutes apart are the criteria recommended for intervention.15

In patients with SAH, there is also no clear evidence-supported management strategy. Hypertension should be avoided in patients with a ruptured aneurysm by administering intravenous titratable agents, as described previously. Some experts argue that relative hypotension should be induced based on the theory that a ruptured aneurysm is at risk for rebleeding in the presence of hypertension. Once the aneurysm is secured by interventional techniques, blood pressure is allowed to return to normal levels. The calcium channel antagonist nimodipine is recommended to reduce the chance of ischemia from vasospasm.5,6

Management of increased ICP is conjectural if its existence is unknown. However, basic steps such as elevating the head of the bed, keeping the head midline, and avoiding painful stimulation are clearly indicated. Hyperventilation with the goal of reducing ICP is currently out of favor. Steroids have no proven benefit in patients with intracranial hemorrhage. Use of osmotic agents such as mannitol in cases in which a herniation syndrome is present may be useful as a temporizing measure when decompressive neurosurgical therapy is planned.

ICP monitoring may be useful in the ED but should be performed under the direction of a neurosurgeon or neurointensivist. Ventriculostomy may be performed in the ED by a neurosurgeon.

If a patient with intracranial hemorrhage has a seizure, the use of anticonvulsants is clearly indicated. Phenytoin and fosphenytoin are the current drugs of choice. Increasingly, levetiracetam seems to be used in these settings, though rigorous evidence for superiority is lacking. Use of anticonvulsants is common in patients with intracerebral hematomas who have not had seizures, although their efficacy is not based on evidence. Likewise, use of anticonvulsants in patients with SAH who have not had seizures is controversial.

Hyperglycemia and hyperthermia are associated with neuronal injury and should be avoided if possible and treated if present. No specific guidelines exist for the clinician at this time. If a coagulopathy is detected, appropriate treatment should be initiated (see the following discussion on warfarin coagulopathy).

In patients with intracranial hemorrhage, most activity in the ED is directed at diagnosis. Treatment is governed by the type of hemorrhage, its cause, and any associated medical and surgical conditions. Definitive treatment is under the direction of the consulting and admitting physicians, and the EP should work in concert with them. In most institutions, SAH and traumatic hemorrhage will be managed by neurosurgeons. Intracerebral hemorrhage is also often managed by neurosurgeons, but institutional management patterns vary. Intensive care and monitoring are necessary in many cases.

For deeply comatose patients, intensive supportive care is indicated in the short term. Evidence of the development of hydrocephalus on CT should lead to consideration of ventriculostomy. Drainage of cerebrospinal fluid and other supportive measures may be guided by continuous measurement of ICP by a variety of invasive techniques.

Cerebellar hemorrhage is an emergency requiring removal of the hematoma and relief of brainstem compression, which offers the possibility of good recovery in selected cases.1 Surgery for removal of supratentorial intracerebral hematomas is controversial and not generally recommended.17 Other inpatient supportive measures for intracerebral hemorrhage might include prophylaxis for thromboembolic events.

Patients with an acute intracerebral hematoma who are taking warfarin should receive fresh frozen plasma (FFP) and vitamin K as soon as possible to correct the coagulopathy. The best dosing regimens are not known, but for patients with a prolonged international normalized ratio, a reasonable recommendation is 5-10 mg of vitamin K (administered intravenously over a 10-minute period) plus 10 mL/kg of FFP administered as soon as possible. Type AB FFP is available in some blood banks and can speed administration time by eliminating the time needed for cross-matching. Institutional recommendation many vary. Time to treatment of warfarin-associated coagulopathy in patients with intracerebral hemorrhage has been found to be the most important determinant of 14-hour reversal of anticoagulation.18
Antiplatelet therapy has been noted to be associated with clinical deterioration.

Acute administration of recombinant activated factor VII limits expansion of hematomas, but it has limited use for thromboembolic complications.\textsuperscript{19,20} Other procoagulant pharmaceutical preparations are under study.

In recent years the trend has continued for early surgical intervention for SAH—that is, intervention to isolate the aneurysm or occlude it within 1 to 2 days of bleeding.\textsuperscript{5,6} Until the aneurysm is secured, the consensus is that blood pressure should be lowered with parenteral medications if necessary. A recent study reported that interventional endovascular coiling may lead to better outcomes in selected patients with ruptured aneurysms.\textsuperscript{21}

Treatment of arteriovenous malformations is complex, controversial, and outside the practice of EPs other than providing supportive care as outlined previously. The risk for rebleeding is less than that with saccular aneurysms. Should seizures occur, anticonvulsant medication should be administered. Additional diagnostic vascular studies besides cranial CT are required and may include angiography, CT angiography, and MRI. Treatment may include radiotherapy, embolization of the arteriovenous malformation, resection, or any combination of these modalities.

All but the smallest epidural hematomas must be treated by craniotomy and surgical evacuation plus investigation of the bleeding site to secure hemostasis. Treatment of subdural hematomas depends on the size and chronicity of the hematoma, the general medical condition of the patient, and signs and symptoms referable to the hematoma. In some patients, chronic subdural hematomas may be of large size with seemingly minimal or no effect on the patient; the problem is underlying atrophy, with the subdural hematoma filling the void. Acute subdural hematomas are generally evacuated if they are causing any mass effect, but at times this may be difficult to assess because the underlying brain is usually injured and edematous.

In hemorrhages complicating abscesses, tumors, or other conditions, treatment is generally directed at the underlying lesion.

\textbf{FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION}

If the facility does not have the necessary specialty care, the patient should be transferred after stabilization to an appropriate facility. The urgency of transport corresponds roughly with the clinical condition of the patient; for example, patients with a headache, a chronic subdural hematoma, and no other findings may probably be transferred electively. The necessity for transfer of stable alert patients with minimal symptoms and minute traumatic hemorrhages detected on CT has not been studied. The notable exceptions in which emergency transport is indicated include acute SAH, cerebellar hemorrhage, and epidural hematoma when the natural history includes early clinical deterioration.

vascular dementia (15% to 25%), Lewy body dementia (5%), and Parkinson dementia (5%).

DELIRIUM

PATHOPHYSIOLOGY

The exact mechanism of delirium is not known, but it is believed to arise from an imbalance of neurotransmitters at the cortical and subcortical levels. The principal neurotransmitters implicated in causing delirium include dopamine, an excitatory neurotransmitter, and acetylcholine and γ-aminobutyric acid, inhibiting neurotransmitters. Physiologic stressors such as infection, medications, and metabolic disturbances can alter the balance of the levels of neurotransmitters and lead to changes in cognition and attention. Inflammatory mediators such as cytokines and histamines are thought to be involved as well.

PRESENTING SIGNS AND SYMPTOMS

Delirium is a syndrome and not a specific disease; therefore, identifying the underlying cause requires a comprehensive approach that includes a medical and family history, physical examination, bedside cognitive assessment, and diagnostic testing. The confusion assessment method is a useful tool to screen for delirium in the medical setting. In an uncooperative or severely confused patient, information obtained from emergency medical service personnel and the patient’s family, personal items brought in with the patient, and a detailed physical examination with close attention to vital signs are important. Figure 104.1 provides a structured approach to assessing cognition at the bedside; patients who are oriented with immediate recall and the ability to sustain attention and recite months or digits in reverse but no delayed recall are unlikely to have delirium and should be suspected of having dementia. The EP should consider all possible reversible medical causes of delirium so that treatment can be initiated as soon as possible (Box 104.1).

Infection

One of the most common causes of delirium in the elderly is infection. A simple urinary tract infection or pneumonia, which is easily handled by the immune system of a healthy adult, can have deleterious effects on the mental balance of an elderly patient who has little physiologic reserve. Progression to sepsis often worsens the delirium and can lead to
Hyponatremia can cause delirium, but it is related to the rate of sodium reduction and not the absolute quantity. A patient with a slight, sudden decrease in serum sodium can have delirium, whereas a larger, more gradual reduction (over days) is well tolerated by many patients. Hyponatremia has many causes, from underlying medical conditions such as the coma. A history of recent coughing, fever, or urinary symptoms can help establish the diagnosis of delirium in elderly patients. Central nervous system infections range from localized abscess, meningitis, and encephalitis to late manifestations of syphilis. All these disease forms may be accompanied by symptoms of delirium ranging from minimal changes in mental status to severe confusion.

**Metabolic, Fluid, and Electrolyte Disturbances**

Hypoglycemia is a common cause of delirium seen in the ED and one that is readily treatable. Patients can have symptoms ranging from mild agitation to coma. As a note of caution, delirium from hypoglycemia may not be suspected in patients with a hypoglycemia-induced focal neurologic deficit or seizure. A history of diabetes, medications, and the time of the last meal are important; documentation of the administration of dextrose and other medications by the emergency medical service should be obtained.

Diabetic ketoacidosis and hyperosmolar hyperglycemic nonketotic coma can both be manifested as an acute confusional state. Hyperosmolar hyperglycemic nonketotic coma is seen more commonly in elderly patients with no history of diabetes or in patients with adult-onset diabetes and an underlying stressor such as infection.

Hyponatremia can cause delirium, but it is related to the rate of sodium reduction and not the absolute quantity. A patient with a slight, sudden decrease in serum sodium can have delirium, whereas a larger, more gradual reduction (over days) is well tolerated by many patients. Hyponatremia has many causes, from underlying medical conditions such as the

**Fig. 104.1 Bedside assessment of cognition.** MMSE, Mini-Mental State Examination; R/O, rule out.
syndrome of inappropriate secretion of antidiuretic hormone to intentional and unintentional water ingestion.

Hypercalcemia may be associated with delirium. The normal range of total serum calcium is between 8.5 and 10.5 mg/dL. Patients with calcium elevated above this range can exhibit confusion, depending on the rate of increase. Patients with end-stage kidney and liver disease can also have delirium. The patient’s medical history or family members may document dialysis or a history of encephalopathy. The underlying process causing the encephalopathy, such as infection or lack of compliance with treatment, should be investigated.

**Drug Withdrawal**

Alcohol withdrawal in its severe form can cause delirium, which is known as delirium tremens. These patients will be seen in the ED with agitation and possible confusion. Visual or auditory hallucinations (or both) and delusions can also be part of the clinical findings and can contribute to misdiagnosis in these patients with a primary psychiatric disorder. Diagnosis of delirium tremens is based on a history of chronic alcohol abuse and symptoms of acute confusion and sympathetic hyperactivity. Typically, the last drink of alcohol was more than 48 hours before arrival at the ED. Vital signs may show severe hypertension, hyperthermia, and tachycardia. On physical examination, the patient often exhibits postural tremor and hyperreflexia.

Withdrawal from chronic benzodiazepine abuse can have a similar manifestation, although the onset of the symptoms varies, depending on the time of the last dose and the half-life of the drug.

**Drug Toxicity**

Alcohol intoxication is a common finding in the ED. The patient is often agitated, confused, and combative. This patient population is more susceptible to other causes of delirium, including infection, trauma, and concomitant ingestion of drugs; a thorough, unbiased evaluation is therefore important.

Common classes of abused drugs causing delirium include sympathomimetics such as cocaine and amphetamine and hallucinogens such as lysergic acid diethylamide (LSD) and ketamine. Close attention to vital signs and identification of a toxic syndrome (toxidrome) are essential in making the diagnosis. Patients with sympathomimetic toxicity may have significant increases in heart rate, blood pressure, and temperature with associated hyperactivity, agitation, and diaphoresis. Clinical findings associated with ketamine abuse include vertical and rotatory nystagmus, midpositioned pupils, hallucinations, labile affect, hyperthermia, and muscle rigidity. Mild tachycardia and hypertension may be seen. Investigation of personal belongings for pills and interview with family members may augment the diagnosis. Anticholinergic medications are also commonly used in the ED and outpatient settings. Delirium associated with mydriasis, hyperthermia, anhydrosis, and hyperemia is seen in this toxidrome.

Many commonly prescribed medications can cause delirium as a result of improper dosing, change in metabolism, intentional overdose, and drug-drug interactions (Box 104.2).

**Cerebrovascular Disorders**

Delirium is a common complication after an acute stroke and is reported in up to 48% of patients. Despite case reports of delirium being the primary manifestation of an acute stroke, it is more frequently reported as a sequela of the event. Delirium has been associated with left-sided infarcts and thalamic and caudate nucleus strokes. Delirium after stroke has been linked to longer hospital stay and increased mortality.

Hypertensive emergency is associated with delirium if target organ damage affects the brain and causes hypertensive encephalopathy. Blood pressure is typically elevated significantly. Other signs of end-organ damage include heart failure and renal failure.

Delirium can develop as a result of a primary traumatic brain injury or the consequent secondary injury. Aggressive systematic evaluation of the reversible secondary causes of acute confusion after a traumatic brain injury is necessary while maintaining optimal cerebral perfusion and oxygenation. Intracerebral bleeding or edema, or both, must be suspected in patients in whom a change in mental status develops after a traumatic brain injury.

**Hypoxemia and Hypercapnia**

Acute elevations in PCO₂ and low Po₂ can cause alterations in cognition and awareness. Pulmonary disorders such as pneumonia, pulmonary embolism, asthma, and pneumothorax

**Box 104.2 Medications Associated with Delirium**

- **Anticholinergics**
  - H₁ receptor blockers (diphenhydramine, meclizine, hydroxyzine)
  - Antiparkinson drugs (benztpmine)
  - Phenothiazine (promethazine)
- **Antidepressants**
  - Tricyclics (amitriptyline, nortriptyline)
  - Selective serotonin reuptake inhibitors (fluoxetine, sertraline)
- **Sedatives**
  - Benzodiazepine (alprazolam, diazepam)
- **Analgesics**
  - Opioids (codeine, morphine)
- **Antinflammatory Agents**
  - Nonsteroidal antiinflammatory drugs (aspirin, ibuprofen)
  - Corticosteroids (hydrocortisone, prednisone)
- **Antihypertensives and Antiarrhythmics**
  - Beta-blockers (metoprolol, propranolol)
  - Angiotensin-converting enzyme inhibitors (lisinopril, captopril)
  - Calcium channel blockers (amlodipine, nifedipine)
  - Other (digoxin)
- **Antibiotics**
  - Quinolones (levofloxacin, ciprofloxacin)
  - Macrolides (azithromycin, clarithromycin)
- **Anticonvulsive Agents**
  - Barbiturates (phenobarbital)
can cause hypoxia. Abnormal chest excursion and rate, depth, and effort of breathing are significant findings on the physical examination. Symptoms important in the history include dyspnea, fever, cough, and pleuritic chest pain, as well as recent travel and a family history of connective tissue disease.

Hypercapnia is a normal finding in many patients with chronic obstructive pulmonary disease, but an acute rise in $P_{CO_2}$ can lead to an alteration in consciousness. Oxygenation is not an adequate measurement of ventilation, and therefore serial monitoring of the patient’s mental status should be initiated in the absence of bedside capnography.

**Endocrine Disorders**

Patients with endocrine disorders such as hyperthyroidism, hypothyroidism, Cushing syndrome, and hyperparathyroidism may have altered mental status when seen initially in the ED. Delirium is more common with severe manifestations of these diseases, as in the case of thyroid storm and myxedema coma. Abnormalities in vital signs, such as tachycardia and fever in thyroid storm and bradycardia and hypotension in myxedema coma, may be the only initial clues to the diagnosis.

**Chemical Exposure**

Delirium may be the initial symptom in patients exposed to a chemical weapon or contaminated environment. History of the exposure is important, but the patient often displays confusion and no history is available. If chemical exposure is suspected, the patient must be brought to the proper decontamination area immediately. Universal precautions should be practiced, as well as use of a proper-level hazmat suit. The patient should be stabilized and evaluated for findings on examination and vital signs suggesting the cause of the contamination and thus the antidote (Box 104.3).

**Environmental Agents**

Stroke from heat exposure occurs in the very young and the elderly, but exertional heatstroke can occur acutely in persons of all age. Heatstroke can be manifested as confusion, hyperthermia (temperature typically higher than 40° C), tachycardia, tachypnea, and hypotension. Delirium may be the initial finding because the central nervous system is often the first organ system to be affected by the elevation in temperature.

In contrast to heat illnesses, patients suffering from cold exposure can exhibit acute confusion. Patients with temperatures below 35° C can demonstrate apathy, slurred speech, confusion, forgetfulness, and shivering. As the temperature drops further, the symptoms progress from delirium to coma. Exposure to plants, insect stings, and animal bites may all result in delirium related to the toxin or chemical involved in the exposure. The initial finding may be related to the cause of the injury or rash, but progression to systemic complications can ensue rapidly.

**Central Nervous System Disease**

Depending on the location of the mass, intracerebral tumors can be manifested as delirium without focal motor deficits. Frontal lobe tumors are more commonly associated with acute changes in personality or behavior.

Absence seizures, seen primarily in children 5 to 10 years of age, are characterized by acute-onset altered mental status without motor activity. The seizure episodes typically last for seconds and resolve without a postictal state. Complex partial seizures can also be accompanied by an acute change in mental status. Patients with nonconvulsive status epilepticus (absence or complex partial) may have a change in mental status that can vary in intensity and duration. Nonconvulsive status can occur in patients of all ages and without any previous history of a seizure disorder. Clinical findings vary from a minor change in mental status to full-blown psychotic or comatose states. The hallmark of nonconvulsive status epilepticus is a change in mental status that occurs in the absence of motor activity and is associated with characteristic electroencephalographic changes. Motor activity, when present, is subtle and in the form of mild twitching of the lips or the upper or lower extremities, but no clear tonic-clonic activity is present.

**Vitamin Deficiency**

Deficiency in certain vitamins can cause altered mental status. Patients with Wernicke encephalopathy, which is caused by a deficiency of thiamine (vitamin B$_1$), can exhibit delirium, ataxia, and ophthalmoplegia. Advanced cases of vitamin B$_2$ deficiency can also cause altered mental status, along with a history of paresthesias, weakness, diarrhea, and loss of appetite.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

If delirium is excluded after a thorough work-up of a patient with confusion, other causes of altered cognition should be considered. An elderly patient with newly recognized or worsening dementia may arrive at the ED with an acute decline in consciousness. Family members may recall changes in memory and function over a longer period, thus suggesting dementia rather than delirium (Table 104.1).

First-time manifestations of psychiatric disorders or exacerbation of underlying psychiatric disease can often be confused with delirium as a result of their similar characteristics. Because patients with psychiatric illness can exhibit delirium, medical and reversible causes of the confusion must be excluded before transfer of care to a psychiatrist (see the

**TREATMENT**

Once the cause of the delirium is discovered, appropriate treatment should be initiated immediately. Antibiotic therapy should be started in patients with suspected meningitis, hypoglycemia should be corrected with dextrose, and patients with hypoxia should receive oxygen supplementation. Delay in diagnosis and treatment can increase overall morbidity and mortality.

Pharmacologic management of agitation is sometimes necessary when a patient with delirium is a danger to self or others or if the agitation is impeding medical evaluation and management. Current pharmacologic options include typical and atypical antipsychotic agents and benzodiazepines. Both droperidol and haloperidol are generally safe and effective and cause less respiratory depression than benzodiazepines do. However, the benzodiazepines, midazolam or lorazepam, may be preferable in particular clinical scenarios such as drug withdrawal or overdose. It is important to remember to reduce dosing in elderly patients because they have altered pharmacodynamics and pharmacokinetics. There is currently no good literature to support the use of atypical antipsychotics in the acute management of delirium.

**DEMENTIA**

**PATHOPHYSIOLOGY**

At the anatomic level, Alzheimer dementia is characterized by atrophy of both cortical and subcortical structures, which is seen most prominently in the hippocampus and temporal cortex. Histologic examination reveals an accumulation of extracellular amyloid plaques and neurofibrillary tangles that attract inflammatory mediators and impede delivery of neurotransmitters along the axons, respectively. Deficiencies in the neurotransmitters acetylcholine and norepinephrine are also thought to be responsible for the dementia in Alzheimer disease. Pathophysiologic and clinical characteristics of the types of dementia are presented in Table 104.2.

**Tests Useful in the Diagnosis of Delirium**

**Infections**
- Pneumonia—Chest radiography, blood culture
- Urinary tract infection—Urinalysis, urine culture
- Human immunodeficiency virus—Head contrast-enhanced CT, lumbar puncture

**Metabolic Disorders**
- Hypoglycemia, hyperglycemia—Glucose fingerstick test, serum chemistry panel
- Electrolyte abnormalities—Serum chemistry panel, ECG
- Hypovolemia—Vital signs, hematocrit
- Uremic encephalopathy—Blood urea nitrogen, serum chemistry panel

**Drugs**
- Withdrawal—History and vital signs
- Illicit and abuse—History and vital signs

**Cerebrovascular Disorders**
- Hypertensive emergency—ECG, serum chemistry panel
- Stroke—Head CT and/or head MRI, ECG, radiography
- Intracerebral bleeding, axonal injury—Head CT

**Hypoxia and Hypercapnia**
- Asthma and chronic obstructive pulmonary disease—Pulse oximetry, capnography
- Pulmonary embolism—V/Q scan or CT angiography of the chest, D-dimer
- Carbon monoxide—Carboxyhemoglobin level, CO-oximetry
- Methemoglobinemia—Serum methemoglobin level, CO-oximetry

**Endocrine Disorders**
- Thyroid storm—Vital signs
- Myxedema coma—ECG, serum chemistry panel, glucose fingerstick test
- Acute adrenal failure—Serum chemistry panel (K ↑, Na ↓, glucose ↓)

**Toxic Exposure**
- Pesticides—Toxidrome

**Thermal Disorders**
- Heat stroke—Temperature, ECG, liver function test, serum chemistry panel
- Hypothermia—Temperature, ECG

**Central Nervous System Disorders**
- Meningitis and encephalitis—Lumbar puncture
- Abscess—Head contrast-enhanced CT or MRI
- Mass—Head CT
- Seizure—Head CT

**Vitamin Deficiency**
- Vitamins B₁ and B₁₂—Serum vitamin assays

CT, Computed tomography; ECG, electrocardiogram; MRI, magnetic resonance imaging; V/Q, ventilation-perfusion.
**PRESENTING SIGNS AND SYMPTOMS**

Alzheimer disease is characterized by a gradual onset of dementia, as defined by the Diagnostic and Statistical Manual of Mental Disorders, fourth edition (Box 104.4), with continuous functional decline. The cognitive impairment seen in Alzheimer disease is not explained by other causes of dementia. Most patients in the ED with Alzheimer disease will already carry the diagnosis and probably have an associated complication such as infection or exacerbation of the dementia.

Because the clinical manifestation of dementia is subtle and gradual, it is important to maintain a high index of suspicion in the evaluation of elderly patients in the ED. Initial symptoms, such as depression, fatigue, insomnia, and irritability, can be nonspecific. Inquiring about missing appointments and increased forgetfulness can be helpful, but patients often avoid discussing difficulties in cognitive abilities by changing the subject. Family members or caregivers may bring patients to the ED because they are unable to care for them or because the patients are no longer able to care for themselves. It is important to recognize early dementia (mild cognitive impairment) in the ED setting to prevent secondary complications such as injuries from falls and fires, noncompliance with medications, and malnutrition and dehydration. Evaluation for a reversible cause of dementia and delirium must be initiated.

Although dementia has a reversible cause in less than 5% of these patients, a thorough history and physical examination must be undertaken to identify this subcategory (see the Priority Actions box “Tests Useful in the Diagnosis of Reversible Causes of Dementia”). Normal-pressure hydrocephalus is characterized by ataxia, urinary incontinence, and dementia, all of which are reversible. Diagnosis is made by CT scan of the head and the finding of elevated opening pressure on lumbar puncture. Treatment is surgical insertion of a shunt.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Pseudodementia is a term used to describe patients who appear to be demented but are actually severely depressed. Differences from genuine dementia can be subtle; patients with pseudodementia usually have a preexisting history of depression with acute onset (often after a specific event), emphasize and appear more distressed about the cognitive deficits, and have preserved attention. If the diagnosis of depression is suspected, patients should be asked about thoughts of suicidality and their social support structure. Appropriate consultation and follow-up with a psychiatrist or social worker or hospitalization may be necessary to ensure the patient’s safety.

---

**BOX 104.4 DSM-IV Criteria for Dementia**

1. Memory impairment (inability to learn new information or to recall previously learned information)
2. At least one of the following:
   a. Aphasasia (language disturbance)
   b. Apraxia (problems with motor activities despite intact motor function)
   c. Agnosia (problems recognizing or identifying objects despite intact sensory function)
   d. Disturbance in executive functioning (planning, organizing, sequencing, abstracting)
3. The deficits listed above significantly impair social or occupational functioning and are a significant decline from a previous level of functioning.
4. The deficits do not occur exclusively during the course of an episode of delirium.
5. The deficits are not better accounted for by another disorder.

---

</tbody>
</table>
As with the treatment of delirium, reversible causes of dementia should be addressed and treatment initiated immediately. Frequently, the dementia will have no reversible cause; the patient has a new diagnosis of dementia or worsening of an underlying condition. In such cases, disposition is based on the patient’s ability to function independently at home or on the family’s capacity to care for the patient. If the family is unable to further care for the patient, admission to the hospital for evaluation for nursing home placement or assisted home care is necessary. If there is adequate support by family and patient safety can be ensured, the work-up of patients with new-onset dementia can be done in an outpatient setting with appropriate coordinated care by the primary physician.

Cholinesterase inhibitors are often used in the treatment of mild to moderate Alzheimer-type dementia; vitamin E has also been recommended to slow the progression of Alzheimer dementia.17 Cholinesterase inhibitors have been recommended to improve quality of life and cognitive function. However, despite the frequent use of these medications, the literature on the benefit of cholinesterase inhibitors remains controversial.18

Disposition depends on the cause of the delirium or dementia and the patient’s response to treatment. If the patient does not improve or the cause is not found, the patient should be transferred to the appropriate inpatient facility. In some cases, with improvement in baseline values the patient can be discharged home.

Other diseases with high morbidity. Although performance of LP is considered relatively safe, patients with a suspected mass lesion or ventricular obstruction may have a theoretic risk for herniation; in such cases neuroimaging may be warranted before LP.1

PROCEDURE
After explaining the procedure to the patient and obtaining informed consent, the patient is placed on the side on a flat stretcher with a pillow under the head. The procedure is typically started with the patient placed in the fetal position and the person performing the procedure seated facing the patient’s back. Administration of a small dose of an anxiolytic, such as midazolam, is helpful in anxious patients. Depending on the response to the medication, pulse oximetry may be appropriate.

The iliac crest is located and the thumbs used to palpate and identify the spinous processes in the midline of the back. This is roughly the L4-L5 interspace and is an appropriate interspace to use. In adults, the L3-L4 interspace can also be used because both lie below the termination of the spinal cord within the spinal canal. An absorbent towel is placed under the patient, and the patient’s back is cleansed with the skin preparation solution (povidone-iodine or chlorhexidine) by making circular motions to scrub the back in gradually expanding circles, starting at the midline of the L4-L5 interspace and out to the iliac crests and lower thoracic spine; the skin should be allowed to dry between wipes (Figs. 105-1 and 105-2). The procedure may be facilitated by having the patient sit and lean over a bedside table while being stabilized by a helper, but this prevents measurement of OP. In anatomically challenging patients, ultrasonography and fluoroscopic guidance may aid in the identification of landmarks.

Once the patient and physician are in positions of comfort, the landmarks are reassessed and lidocaine is injected subcutaneously with a 27- or 25-gauge needle at the identified interspace to anesthetize the skin (Fig. 105.3). In children, topical application of anesthetic before injection may reduce the initial discomfort. After 1 to 2 minutes the deeper tissues are anesthetized by advancing a longer, 22-gauge needle slowly and injecting lidocaine. Achieving sufficient anesthesia is critical to success of the procedure.

Once anesthesia is achieved, the landmarks are checked yet again. A smaller-gauge needle with the bevel of the needle angled parallel to the dural fibers or use of a small-diameter blunt-tipped needle will decrease the frequency of post–dural puncture headache.
to caudad, to minimize the incidence of post–dural puncture headache (PDPH). The needle is advanced slowly while controlling it at the skin with the nondominant hand. Angling the needle slightly cephalad may be required because of the orientation of the spinous processes. The widely discussed “pop” of the needle penetrating the dura is not always felt; after traversing the ligamentum flavum, removal of the introducer every few millimeters of advancement may identify CSF. It is important to keep the orientation of the needle in the midline to avoid nerve roots as they exit the spinal canal.

Once CSF is observed, the manometer is attached to measure OP (Fig. 105.5). The patient’s legs are straightened while the patient is lying on the side, and the EP waits for CSF to equilibrate in the manometer column (slight respiratory variation will be noted) (Fig. 105.6). The fluid meniscus is the OP, which in the absence of obstructive hydrocephalus is equivalent to ICP.

One to 2 mL of CSF is placed into each of four tubes, the introducer stylet is replaced in the needle, the needle is
removed from the patient’s back, and pressure is briefly applied over the puncture site with a piece of gauze. Residual skin preparation solution is washed off and a bandage applied over the puncture site. At this point the patient may be returned to any position of comfort.

**COMPLICATIONS**

PDPH is the most common complication associated with LP, with a rough incidence of 5% to 40%. Factors associated with PDPH include the technique and the type and gauge of needle used. PDPH develops about 2 days after the performance of a dural puncture, is worse with standing, and is partially relieved by lying down. The exact cause of this complication is uncertain, but it possibly due to continued leakage of CSF through the dural rent created by the needle. The headache is typically self-limited but can last up to a week and be fairly debilitating.

Several strategies can be used to reduce the incidence of PDPH, including orientation of the bevel of sharp-tipped needles parallel to the dural fibers to avoid cross-cutting of the fibers, the use of atraumatic blunt-tipped spinal needles (Pajunk, Sprotte) with a noncutting tip and side port, and reinsertion of the introducer into the noncutting needle before removal of the needle. The patient’s position following dural puncture or the periprocedural use of intravenous (IV) fluids is not associated with the development or prevention of PDPH. PDPH can be treated by reassurance and administration of IV fluids, analgesics, and IV caffeine. Severe headaches may require the placement of a blood patch, which is curative in 80% to 90% of cases. Other complications of LP are less common, but potentially more serious. Development of a spinal epidural hematoma is more common in the setting of anticoagulation, platelet disorders, thrombocytopenia, and hypocoagulable conditions and may represent a surgical emergency. As with all invasive procedures, infections such as vertebral osteomyelitis, meningitis, or abscess can be minimized by observing strict sterile technique. In procedures performed at the proper level (i.e., L3-L4 or lower in an adult and L4-L5 or lower in a child), cauda equina or nerve root injury is not a common complication.

**CEREBROSPINAL FLUID ANALYSIS**

CSF testing varies depending on the indication for LP. If central nervous system (CNS) infection is suspected, a Gram stain and bacterial culture should be obtained. This may be performed on any CSF sample because all fluid should be sterile. CSF cultures, assays, or tests for other organisms should be ordered as indicated, including viral and fungal cultures, assay for cryptococcal antigen, India ink, testing for acid-fast bacilli, and other specific pathogens. Some of these assays may require more than 1 to 2 mL of CSF, so extra fluid should be obtained from immunocompromised patients or when unusual pathogens are suspected.

In the setting of infection, CSF protein concentrations may be elevated and absolute CSF glucose concentrations and CSF-serum glucose ratios are often depressed. In general, when CSF analysis reveals high protein and low glucose concentrations relative to serum glucose, the EP should maintain a high index of suspicion for infection.

CSF cell counts must be determined in the setting of infection, primarily to assess the number and type of leukocytes present in the CSF. If the CSF obtained during LP is obviously bloody or blood-tinged, cell counts should be performed on multiple tubes and the number of leukocytes corrected for the number of erythrocytes present. The typical anecdotal correction applied in the past is 1 leukocyte for every 500 erythrocytes in a traumatic tap. More than 5 leukocytes per high-power field in CSF is considered abnormal, although CNS infections typically yield higher values. Lower leukocyte counts still above the cutoff may also signify CNS vasculitis, viral infection, or malignancy, depending on the cell type present.

When concern for SAH exists, cell counts obtained from tubes 1 and 4 should be used for comparison. A specific value has not been established to determine the number of erythrocytes that differentiate a traumatic tap from SAH; however, the number of cells in the last tube collected should be substantially less than those in the first sample collected in the setting of a traumatic tap. CSF should also be analyzed for the presence of xanthochromia (yellow discoloration) when SAH is suspected, preferably by spectrophotometry for maximum sensitivity and specificity. Xanthochromia from erythrocyte lysis and enzymatic degradation of hemoglobin in CSF develops 12 hours after the initial hemorrhage. The presence of xanthochromia suggests SAH versus traumatic LP; its absence immediately after the onset of symptoms does not rule out SAH, however. Xanthochromia persists for at least 1 week, and its presence thereafter suggests repeated bleeding or an alternative explanation.

**INTRACRANIAL PRESSURE MONITORING**

Placement of an invasive ICP monitor is typically performed in the setting of traumatic brain injury (TBI). Patients with suspected TBI and an associated Glasgow Coma Scale score of 7 to 8 or less often require ICP monitoring because an adequate neurologic examination may be difficult to perform in these patients. Sustained elevations in ICP greater than 15 to 20 mm Hg, are associated with worse clinical outcomes. To assess ICP in patients with an unreliable neurologic...
examination, a monitor can be placed directly overlying the dura or into the ventricles. When performed on an emergency basis in the ED, these devices are typically placed by neurosurgeons in sterile fashion at the bedside. Furthermore, placement of an invasive monitor should be reserved for patients with some chance for meaningful recovery from their injuries.

**VENTRICULOPERITONEAL SHUNT ASPIRATION**

VP shunts are placed for persistent hydrocephalus caused by congenital malformations, previous SAH, obstructive processes such as neoplasms, and normal-pressure hydrocephalus. Aspiration of a VP shunt is typically performed when CNS infection is suspected in patients seen in the ED with headache, fever, or altered mental status. The reservoir can also be used to aspirate larger volumes of CSF in the setting of a malfunctioning shunt and acute hydrocephalus. A standard shunt assembly consists of a catheter tip located in the ventricle, shunt tubing traversing the cerebrum and exiting the skull, and a CSF reservoir and check valve placed subcutaneously under the scalp. The shunt is tunneled down the neck and empties into the peritoneum. Shunt aspiration is a relatively simple procedure that involves palpation of the reservoir under the scalp as a landmark. Once the landmark is identified, the skin is prepared in sterile fashion. Absolute sterility is imperative because the procedure violates the sterile space of the CNS through a retained foreign body (i.e., the shunt) and infection can result.

The location of the reservoir is subcutaneous, so its depth below the skin and therefore the depth of needle penetration should be only the thickness of the scalp. Once sterility is ensured, a 23- or 25-gauge butterfly needle is introduced into the reservoir, with the bevel of the needle contained within the reservoir. If desired, a manometer can be connected to the butterfly needle so that pressure within the CNS can be assessed. If so, a larger-gauge needle such as a 23 gauge may be needed to produce more accurate results. CSF is then aspirated for standard CSF analysis as discussed previously.

**COMPlications**
The most common complication of VP shunt aspiration is infection, which can potentially result in meningitis or encephalitis. Other complications include subdural hemorrhage from overly aggressive CSF decompression, bleeding or persistent CSF leakage from the site of aspiration, and disruption of the valve by a misplaced attempt at aspiration.

Allergic Disorders
Aaron N. Barksdale and T. Paul Tran

INSECT STINGS
Serious systemic reactions to insect stings are rare and occur in 1% of children and 3% of adults. Anaphylactic reactions account for approximately 50 deaths annually in the United States. There is a 2:1 male-to-female distribution, and adult male agricultural workers are considered the most vulnerable population. Individuals who experience large local reactions are less likely to have a systemic reaction (5% to 10%).

DRUG ALLERGY
A drug allergy is defined as an immune-mediated adverse response to a drug. An adverse drug reaction is defined as a noxious, unintended, or undesired response to a drug taken at a normal dose for the prevention, diagnosis, or treatment of a disease, and a drug side effect is an expected and known (adverse) effect of taking the drug that is not the intended therapeutic outcome. Although the true frequency is unknown, drug allergy is thought to account for approximately one third of adverse drug reactions. Adverse drug reactions affect 10% to 20% of hospitalized patients and more than 7% of the general population.

PATHOPHYSIOLOGY
The immune system protects the host by distinguishing self from nonself; it tolerates the former but attacks the latter. Allergy, allergic diseases, and hypersensitivity reactions arise when our immune system reacts inappropriately to allergens with resultant harm to the host. For allergic diseases to occur, predisposed individuals need to first be exposed to an allergen through a process called sensitization.

Allergy refers to inappropriate responses (hypersensitivity) by the host’s immune system.
Anaphylaxis is an acute, potentially fatal, systemic allergic reaction. Deaths in patients with anaphylaxis are caused by acute respiratory failure.
Foods, medications, and insect stings are the most common agents causing anaphylaxis.
Epinephrine is the first-choice medication in the treatment of anaphylaxis, with H1 and H2 antihistamines and steroids being helpful adjuncts.
Most cases of angioedema are mediated by IgE and respond to allergic therapy. Certain forms of angioedema, however, are mediated by bradykinin and may respond to new classes of medications, the kallikrein inhibitor (ecallantide) and C1 esterase inhibitor concentrates (Cinryze, Berinert).

**KEY POINTS**

- Allergy refers to inappropriate responses (hypersensitivity) by the host’s immune system.
- Anaphylaxis is an acute, potentially fatal, systemic allergic reaction. Deaths in patients with anaphylaxis are caused by acute respiratory failure.
- Foods, medications, and insect stings are the most common agents causing anaphylaxis.
- Epinephrine is the first-choice medication in the treatment of anaphylaxis, with H1 and H2 antihistamines and steroids being helpful adjuncts.
- Most cases of angioedema are mediated by IgE and respond to allergic therapy. Certain forms of angioedema, however, are mediated by bradykinin and may respond to new classes of medications, the kallikrein inhibitor (ecallantide) and C1 esterase inhibitor concentrates (Cinryze, Berinert).

**ALLERGIC DISEASE: ALLERGIC RHINITIS, INSECT STINGS, DRUG ALLERGY**

**EPIDEMIOLOGY**
The prevalence of allergic disorders, including the incidence of anaphylaxis, has been increasing worldwide in the last few decades and is a topic of intensive study. Features of Western lifestyles, such as changes in infant diets, widespread use of antibiotics, smaller family size, and cleaner child care, are believed to reduce stimulatory antigenic exposure in an individual’s early years. This has led to an environment in which the immune system is dominated by a persistent allergy-prone system.

**ALLERGIC RHINITIS**
It is estimated that up to 42% of Americans suffer from some form of allergic rhinitis at any one time, and it has been shown to have a strong correlation with asthma. In recent studies, nearly 40% of adults with allergic rhinitis were also found to have asthma, and 80% of asthmatics demonstrated signs of rhinitis.

**INSECT STINGS**
Serious systemic reactions to insect stings are rare and occur in 1% of children and 3% of adults. Anaphylactic reactions account for approximately 50 deaths annually in the United States. There is a 2:1 male-to-female distribution, and adult male agricultural workers are considered the most vulnerable population. Individuals who experience large local reactions are less likely to have a systemic reaction (5% to 10%).

**DRUG ALLERGY**
A drug allergy is defined as an immune-mediated adverse response to a drug. An adverse drug reaction is defined as a noxious, unintended, or undesired response to a drug taken at a normal dose for the prevention, diagnosis, or treatment of a disease, and a drug side effect is an expected and known (adverse) effect of taking the drug that is not the intended therapeutic outcome. Although the true frequency is unknown, drug allergy is thought to account for approximately one third of adverse drug reactions. Adverse drug reactions affect 10% to 20% of hospitalized patients and more than 7% of the general population.

**PATHOPHYSIOLOGY**
The immune system protects the host by distinguishing self from nonself; it tolerates the former but attacks the latter. Allergy, allergic diseases, and hypersensitivity reactions arise when our immune system reacts inappropriately to allergens with resultant harm to the host. For allergic diseases to occur, predisposed individuals need to first be exposed to an allergen through a process called sensitization.

The term atopy is used to describe the propensity in affected patients to produce IgE in response to otherwise innocuous environmental allergens. Atopic patients have higher serum levels of IgE antibody and a propensity for the development of one or more atopic diseases (e.g., allergic asthma, allergic rhinoconjunctivitis, atopic dermatitis, urticaria, angioedema).

Hypersensitivity reactions are mechanistically divided into four types of reactions according to the Gell and Combs classification system (Box 106.1). The immediate hypersensitivity reaction (type I), which is mediated by IgE, serves as the classic model of the immune response to allergen. On initial exposure to allergen, T helper 2 (Th2) cells are activated, which results in the production of an array of cytokines that
exert their effects on the T cells themselves, B cells, and antigen-presenting cells. IgE is elaborated and attached to the high-affinity Fc receptor on the surface of mast cells and basophils. Fixation of allergen-specific IgE leads to a series of cellular and molecular changes that prime these cells for future exposure. On reexposure, allergen cross-links the cell-bound IgE on the surface of mast cells and basophils, thereby setting in motion a complex cascade of events that lead to the release of preformed mediators such as histamine, lipid mediators, and cytokines and subsequent activation of various inflammatory pathways. These mediators and products of secondary inflammatory pathways cause adherence and chemotaxis of inflammatory cells, increased capillary permeability, vasodilation, smooth muscle contraction, and sensory nerve stimulation. A few allergen molecules can thus cause the release of a large number of mediator molecules in a designed amplification response. Examples of type I hypersensitivity reactions include allergic rhinitis, allergic asthma, urticaria, angioedema, and anaphylaxis.

See Box 106.1, Types of Hypersensitivity, online at www.expertconsult.com.

Allergens are typically carbohydrate or protein molecules (or parts of a larger molecule) that elicit an immune response. The inflammation that occurs in allergy is divided into three temporal phases. Early-phase reactions occur within minutes of exposure and are considered immediate type I hypersensitivity reactions. Late-phase reactions typically occur within 2 to 6 hours and peak 6 to 9 hours after exposure. This response is thought to be due to newly synthesized cytokines, growth factors, and chemokines, which were released more slowly than the preformed mediators primarily responsible for the early-phase reaction. This reaction often involves airway narrowing and hypersecretion of mucus in the lungs, in addition to the erythema, warmth, and pain experienced in the skin. In some individuals there is no clinical distinction between the early and late phases. Chronic allergic inflammation is the final phase in the inflammatory process. It occurs after persistent or repetitive exposure to specific allergens and results in tissue remodeling and structural changes in affected cells. Chronic allergic inflammation can further increase epithelial injury, mucus production, and thickening of airway walls.

The majority of serious sting-related reactions are caused by insects belonging to the order Hymenoptera (yellow jackets, hornets, honeybees, wasps, and fire ants). Their venom contains histamine, dopamine, various peptides, and protein enzymes that are either vasoactive or can elicit significant allergic reactions (IgE mediated).

PRESENTING SIGNS AND SYMPTOMS

ALLERGIC RHINITIS
A detailed history is important in making the diagnosis of allergic rhinitis. Patients often acknowledge a history of seasonal allergies (hay fever). Patients with allergic rhinitis frequently suffer from symptoms such as eye itching, swelling, and discharge (clear or can resemble strings of cheese); nasal congestion; itching of the nose; sneezing; rhinorrhea; and mild cough. Patients may report a temporal association with exposure to certain environment allergens (seasonal allergy, pollen, mold, animal dander). On physical examination, the nasal membranes are swollen with enlarged, pale turbinates and a clear nasal discharge. The maxillary sinuses may feel full and tender on palpation.

INSECT STINGS (HYMENOPTERA VENOM ALLERGY)
Patients with systemic allergic reactions from stings may exhibit generalized urticaria, angioedema, wheezing, stridor, anxiety, or other signs of respiratory and circulatory insufficiency. Most stings, however, cause self-limited local reactions consisting of redness, pain, and itching at the site of the sting. These reactions typically develop within minutes and usually last for a few hours. Local reactions rarely put patients at risk for future systemic reactions. Fire ant stings tend to produce pustulelike lesions. Local stings that result in subsequent swelling near the oropharynx (either cutaneous or deep) can cause airway compromise, and affected patients should be observed in the emergency department (ED) until the symptoms have resolved.

DRUG ALLERGY
Most allergic reactions occur within 1 hour of taking the medication, and symptoms typically include urticaria, morbilliform rash, itching (lips, tongue, face), or sensitivity to light. Symptoms of anaphylaxis may also occur (see later in chapter). Late symptoms (1 to 2 weeks) include fever, muscle and joint aches, and swollen lymph nodes.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

ALLERGIC RHINITIS
Box 106.2 lists other diagnostic considerations in patients with symptoms that may mimic allergic rhinitis. Patients older than 20 years should be investigated for nonallergic causes (e.g., polyps). Atopic patients with severely inflamed conjunctivae, lids, and periorbital structures should raise the possibility of atopic keratoconjunctivitis (Fig. 106.1) and vernal keratoconjunctivitis (Fig. 106.2). These two types of chronic allergic conjunctivitis have the potential to cause corneal erosions and ulcers leading to vision loss and should be managed in consultation with an ophthalmologist.

Typically, no diagnostic tests need to be performed in the ED. Specific IgE serum assays such as the radioallergosorbent test (RAST), enzyme-linked immunosorbent assay (ELISA), skin prick test, and nasal smears are usually performed by allergists.

INSECT STINGS (HYMENOPTERA VENOM ALLERGY)
Considerations include secondary bacterial infection, cellulitis, abscess, urticaria, angioedema, and anaphylactic reaction. Screening laboratory examinations for infection (complete blood count, wound culture) should be done if signs of infection are noted on physical examination.
**BOX 106.1 Types of Hypersensitivity**

**Type I Hypersensitivity**  
Immediate or immunoglobulin E (IgE)-mediated reaction: Binding of antigens to IgE on the surface of mast cells and basophils leads to the release of inflammatory mediators (maximal reaction in 20 minutes). This type of hypersensitivity reaction is seen with allergic diseases, drug reactions, urticaria or angioedema, and anaphylaxis.

**Type II Hypersensitivity**  
Cytotoxic antibody reaction: Binding of antigens to their own cells (or foreign cells with foreign antigens) attracts binding by IgM/IgG antibodies, which subsequently causes injury and lysis of cells via the complement or mononuclear cell system.

**Type III Hypersensitivity**  
Immune complex (IC)-mediated reaction: Binding of antigens to IgE forms soluble ICs, which are deposited on vessel walls and cause a local inflammatory reaction (Arthus reaction) by attaching to FcγRIII receptors on inflammatory cells (maximum reaction, 4 to 8 hours).

**Type IV Hypersensitivity**  
Cell-mediated delayed hypersensitivity reaction: Sensitized lymphocytes (T\textsubscript{H}1 cells) recognize the antigen and recruit additional lymphocytes and mononuclear cells to the site, thereby starting the inflammatory reaction. This type of hypersensitivity reaction is seen with contact dermatitis, erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis (maximum reaction, 48 to 72 hours).
sensitization (the drug was taken before) and typical allergic symptoms (urticaria, angioedema, wheezing).

Common entities to consider are infection (viral exanthem, mononucleosis, Rocky Mountain spotted fever, syphilis, cellulitis, sepsis), insect bite, pityriasis rosea, serum sickness, vasculitides, contact dermatitis, fixed drug eruption, and drug hypersensitivity syndrome.

Diagnosis of an adverse drug reaction relies on a careful history and thorough skin examination. A complete blood count, chemistry panel, and erythrocyte sedimentation rate may be ordered to evaluate possible infections or vasculitis. Skin testing is of limited value. RAST and ELISA for serum IgE require known immunogenic epitopes for the drugs, information that is usually unavailable. In cases of hemolytic anemia, the indirect Coombs test can be used to diagnose immune-mediated destruction of red blood cells.

Studies show that 4.4% of patients whose penicillin allergy history was confirmed by a positive skin test experienced an allergic reaction to cephalosporins. Only 10% to 20% of patients who report a history of penicillin allergy are truly allergic when assessed by skin testing. Although the overall risk for a cross-allergic reaction to cephalosporins in patients with a history of a penicillin allergy is low, the use of cephalosporins requires weighing the risks versus benefits based on an informed discussion between the patient and treating physician. Table 106.1 shows the incidence of allergic reactions to penicillin. Some factors can transiently cause T cells to falsely identify the penicillin epitope as being allergic. For example, up to half (50%) of patients with mononucleosis, a maculopapular rash develops after taking amoxicillin. These same patients often have no adverse drug reaction on subsequent challenge with amoxicillin at a later time. Penicillin allergy should not be diagnosed in such patients.

**DRUG ALLERGY**

Understanding the involvement of an immunologic mechanism in drug allergy may help physicians in determining whether a reaction represents an adverse drug reaction or a true drug allergy. For example, the stomach discomfort that may result from taking nonsteroidal antiinflammatory drugs (NSAIDs) is an adverse drug event and not a drug allergy. Factors that favor a drug allergy include a history of previous sensitization (the drug was taken before) and typical allergic symptoms (urticaria, angioedema, wheezing).

Common entities to consider are infection (viral exanthem, mononucleosis, Rocky Mountain spotted fever, syphilis, cellulitis, sepsis), insect bite, pityriasis rosea, serum sickness, vasculitides, contact dermatitis, fixed drug eruption, and drug hypersensitivity syndrome.

Diagnosis of an adverse drug reaction relies on a careful history and thorough skin examination. A complete blood count, chemistry panel, and erythrocyte sedimentation rate may be ordered to evaluate possible infections or vasculitis. Skin testing is of limited value. RAST and ELISA for serum IgE require known immunogenic epitopes for the drugs, information that is usually unavailable. In cases of hemolytic anemia, the indirect Coombs test can be used to diagnose immune-mediated destruction of red blood cells.

Studies show that 4.4% of patients whose penicillin allergy history was confirmed by a positive skin test experienced an allergic reaction to cephalosporins. Only 10% to 20% of patients who report a history of penicillin allergy are truly allergic when assessed by skin testing. Although the overall risk for a cross-allergic reaction to cephalosporins in patients with a history of a penicillin allergy is low, the use of cephalosporins requires weighing the risks versus benefits based on an informed discussion between the patient and treating physician. Table 106.1 shows the incidence of allergic reactions to penicillin. Some factors can transiently cause T cells to falsely identify the penicillin epitope as being allergic. For example, up to half (50%) of patients with mononucleosis, a maculopapular rash develops after taking amoxicillin. These same patients often have no adverse drug reaction on subsequent challenge with amoxicillin at a later time. Penicillin allergy should not be diagnosed in such patients.

**TREATMENT**

**ALLERGIC RHINITIS**

Oral second-generation H₁ blockers (loratadine, fexofenadine), oral decongestants (pseudoephedrine), and nasal...
decongestants (oxymetazoline, phenylephrine) can be used for mild, intermittent symptoms. Moderate to severe and persistent nasal symptoms may require the addition of intranasal steroid (fluticasone, triamcinolone, budesonide), or chromone derivative such as cromoglycate and nedocromil. An intraocular antihistamine (olopatadine), topical chromone derivative such as cromoglycate and nedocromil, or intraocular ketorolac can be used for ocular allergies, including conjunctivitis.

**INSECT STINGS (HYMENOPTERA VENOM ALLERGY)**
The stinger should be removed if present. For minor local reactions, antihistamines and NSAIDs such as ibuprofen should be sufficient. Ice can be used to decrease the inflammation, and elevation will decrease the swelling. The pseudo-pustules caused by fire ant stings contain mostly necrotic material and should not be unroofed. These lesions should be managed similar to second-degree burns, with the therapeutic goal being pain control and minimization of the risk for secondary bacterial infection.

Treatment of large local reactions includes cold compresses, NSAIDs, H1 antihistamines, and high-potency topical steroids. Prednisone (1 mg/kg or 60 mg orally) as a single dose or for 5 days might decrease local swelling. The swelling typically resolves in 7 to 10 days. Antibiotics should be prescribed only if signs of secondary bacterial infection are present. Coverage for methicillin-resistant *Staphylococcus aureus* should be considered. Management of systemic reactions to stings is similar to that for anaphylaxis.

**DRUG ALLERGY**
The most prudent approach in managing possible drug allergy–related complaints in the ED is to discontinue use of the suspect medication or medications, treat the allergic symptoms, and prescribe a suitable alternative drug or drugs. Severe symptoms should be treated in the same way as anaphylaxis (see Box 106.8). Patients with Stevens-Johnson syndrome and toxic epidermal necrolysis require a multidisciplinary approach that includes an intensivist, burn surgeon, and endocrinologist or allergist. For minor allergic drug reactions, H1 antihistamines can be prescribed for itching, flushing, and rash. Steroids are reserved for serious or extensive drug reactions.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

**ALLERGIC RHINITIS**
Patients are advised to avoid allergens when practically feasible. Those who are sensitive to pollen should minimize time spent outdoors during periods of high pollen counts and lessen the allergen load indoors by keeping windows closed. Use of HEPA (high-efficiency particulate air) filters, infestation control (cockroach), and impermeable covers for mattresses and pillows may also decrease the severity of symptoms.

**INSECT STINGS (HYMENOPTERA VENOM ALLERGY)**
Patients with systemic reactions to stings warrant overnight observation in the hospital. Patients with limited or large local reactions can be managed as outpatients.

Patients with urticaria or angioedema reactions should be referred to an allergist for possible skin testing and venom immunotherapy. These patients should wear a Med-Alert bracelet. Before discharge it is important that patients be educated about prevention of stings (always wearing shoes when outdoors and not wearing brightly colored clothes or fragrances in high-risk areas), the early signs of a systemic reaction, and how to self-administer an Epi-Pen. At least two Epi-Pens should be prescribed for emergency self-injection.

**DRUG ALLERGY**
The majority of patients with late (>1 hour to days) reactions to medications who have a mild to moderate rash can be safely discharged home. Those with immediate drug reactions (<1 hour) need to be observed in the ED. Patients with a systemic reaction whose symptoms resolve after a 4- to 6-hour observation period in the ED can be discharged home in the company of a family member. They should be prescribed two Epi-Pens, H1 antihistamines, a short course of steroids, and a Med-Alert bracelet. Patients at risk for a recurrent systemic drug reaction who have poor social support, comorbid conditions, and moderate to severe allergic syndromes warrant a hospital stay. At the end of the ED visit, patients should be educated about the nature of a drug allergy versus an adverse drug reaction.

URTICARIA

EPIDEMIOLOGY

Urticaria (hives) is a fairly common reaction that affects approximately 20% of the population at some point in their lifetime.18 It has numerous different underlying causes and consists of several different types and subtypes. Spontaneous urticaria is broadly divided into acute (<6 weeks) and chronic (≥6 weeks) forms, with the latter representing approximately 10% to 20% of cases.

PATHOPHYSIOLOGY

The classic wheal lesions associated with urticaria are the result of edema within the mid and upper dermal layers of the skin. Dilation of lymphatic vessels and capillary venules allows extravasation of protein-rich fluid into the surrounding tissue. This complex inflammatory process involves a variable mixture of macrophages, T cells, neutrophils, eosinophils, and mast cells.19

PRESENTING SIGNS AND SYMPTOMS

Patients with urticaria usually have hives of variable duration and location.20,21 Urticarial lesions are pruritic, erythematous, raised rashes that blanch on palpation. The lesions are typically round or oval with serpiginous borders, but they may vary in color, size, and shape (Fig. 106.3). They may be localized or appear throughout the body, but there is a slight predilection for the trunk, hands, feet, lips, tongue, and ears. Urticaria usually starts with erythema (flare) as a result of capillary vasodilation in the superficial layer of the dermis. As the protein-rich fluid extravasates into surrounding tissue, it evolves into raised wheals and may change from red to white. A history of pruritic red rash that changes in size and shape, with extension and regression over a period of hours or days, favors the diagnosis of urticaria.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The first step in narrowing the differential diagnosis of urticaria is to determine whether the urticaria is acute (<6 weeks of symptoms) or chronic (≥6 weeks of symptoms).20,21 The differential diagnosis of urticaria is outlined in Box 106.3 and illustrated in Figure 106.4.

Evaluation of acute urticaria and angioedema is based on a careful history and skin examination; little additional laboratory testing should be needed. The work-up for chronic urticaria is usually performed by an allergist in the office.

TREATMENT

Therapy for acute urticaria includes avoidance of the suspected causative agent and administration of H1 antihistamines (see Fig. 106.4). The second-generation H1 antihistamines (cetirizine, loratadine, fexofenadine, desloratadine) are currently recommended as the first-line drugs.18,20 For urticaria judged difficult to control with antihistamines alone, prednisone can be added.20 If the urticarial rash is extensive and pruritus is severe, epinephrine can be administered (0.3 to 0.5 mL of a 1:1000 dilution intramuscularly). It may be repeated every 1 to 2 hours as needed. Caution is advised when administering epinephrine to patients at risk for coronary heart disease (>35 years of age, other risk factors for coronary artery disease). Patients with chronic urticaria can be prescribed a nonsedating H1 antihistamine (in higher dosages) as a temporizing measure and be referred to an allergist for further care.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Most patients with urticaria (acute and chronic) can be managed as outpatients. Usually, a 7-day course of a second-generation H1 antihistamine is sufficient, although a corticosteroid (prednisone) in a tapering course is sometimes added for moderate to severe cases.

ANGIOEDEMA

EPIDEMIOLOGY

Angioedema (not including hereditary angioedema [HAE]) may affect 10% to 20% of the population at some time in
**BOX 106.3 Differential Diagnosis of Urticaria**

**Foods, Additives**
- Seafood (fish, shellfish, scombroid), tree nuts, eggs, seeds
- Foods containing allergens that are cross-reactive with latex, including bananas, avocados, kiwi fruit, chestnuts
- Food preservatives such as tartrazine, benzoates, and sulfites
- Other: cow’s milk, pork, strawberries, wheat, chocolate, tomatoes

**Medications**
- IgE-mediated: penicillins, sulfonamides, cephalosporins
- Nonimmunologic release of histamine: acetylsalicylic acid, nonsteroidal antiinflammatory drugs, indomethacin, angiotensin-converting enzyme inhibitors, morphine, codeine, acetylcholine, iodinated contrast dye, beta-blockers, vancomycin

**Infections**
- Viral infections: Epstein-Barr virus, hepatitis, coxsackievirus
- Bacterial (occult) infections: sinusitis, dental infections or abscesses, chronic cholecystitis
- Fungal infections: candidiasis, dermatophytosis
- Parasitic infections

**Systemic Disease**
- Rheumatologic or immunologic: vasculitis, serum sickness, systemic lupus erythematosus, juvenile rheumatoid arthritis
- Endocrinologic: thyroid (both hyperthyroid and hypothyroid) disease, progesterone dermatitis, pruritic urticarial papules and plaques of pregnancy, premenstrual flare-up
- Skin disease: mastocytosis, dermatitis herpetiformis, amyloidosis, pemphigoid
- Neoplastic: paraneoplastic syndrome, Hodgkin disease, leukemia

**Inhalants**
- Pollen
- Animal dander
- House mite dust
- Mold spores
- Household chemicals, aerosols

**Hymenoptera**
- Yellow jackets, honeybees, hornets, wasps most commonly reported; fire ants

**Types of Urticaria**
- Dermatographism: may begin suddenly after a viral illness or drug therapy
- Pressure or vibratory urticaria: caused by tight clothing around the waist (may be misdiagnosed as scabies)
- Heat urticaria: may be caused by a rise in core temperature after a hot bath, fever, vigorous exercise (also known as cholinergic urticaria because it can be induced by injection of a cholinergic agent)
- Cold urticaria: caused by exposure to cold temperatures
- Solar urticaria: occurs after exposure to intense sunlight or artificial light (antigens produced in the skin may interact with immunoglobulin E)
- Water urticaria: prickling skin sensation without skin lesions within 15 minutes of contact with water
- Exercise urticaria: may progress to anaphylaxis
- Household chemicals, aerosols
- Contact urticaria: urticarial wheals or hives develop within 30 to 60 minutes after cutaneous exposure to certain agents, including plants (nettles), animals (caterpillars, jellyfish), latex, cosmetics, and various chemicals

their lives; most chronic angioedema is idiopathic. HAE is an autosomal dominant genetic disorder with an estimated prevalence of 1 per 10,000 to 150,000 persons. The incidence of angiotensin-converting enzyme inhibitor (ACEI)-associated angioedema is approximately 0.2% to 0.7% and slightly higher in the African American population. Episodes have been reported to occur within days of initiating ACEI therapy and up to 8 years later, with an average onset of approximately 10 months. Ten percent to 25% of cases of angioedema encountered in the ED are considered to be life-threatening. African Americans are more susceptible to angioedema induced by ACEIs. Other forms of angioedema have no clear association between race and the frequency or severity of the disease. In HAE, affected women tend to have more frequent attacks and a more severe clinical course. Chronic idiopathic angioedema is more common in females than in males.

Angioedema can affect patient of all ages. For patients with HAE, the onset of symptoms is often around puberty. Idiopathic angioedema is more common in those aged 30 to 50 years than in other age groups. Patients typically experience minor swelling in childhood that may go unnoticed, with increased severity noted around puberty. However, type III HAE is found in the second decade of life or later and occurs only rarely before puberty. Five percent of adult HAE carriers are asymptomatic and identified only after their children are found to be symptomatic.

Urticaria-associated angioedema occurs in nearly 50% of children with urticaria. Because urticaria occurs in 2% to 3% of children, urticaria-associated angioedema is estimated to occur in 1% to 2% of the general population.

**PATHOPHYSIOLOGY**

Angioedema (swelling) refers to vasodilation and edema in the lower dermis and subcutaneous layers of the skin. In the majority of cases angioedema shares a similar allergic mechanism, but in selected cases it is the result of a reaction mediated by bradykinin. Both forms of angioedema can appear similar clinically, with bradykinin-mediated angioedema typically being manifested as angioedema without urticaria. They both commonly affect the eyelids, face, lips, and tongue and can potentially cause life-threatening respiratory compromise. It is important to distinguish the two forms because bradykinin-mediated angioedema may respond better to the new classes of medications, including recombinant C1 factor, kallikrein inhibitor, or a bradykinin receptor antagonist.

Bradykinin-mediated angioedema typically falls into one of two groups, HAE or acquired angioedema (AAE). HAE was first described by William Osler in 1888. It is a rare autosomal dominant disorder with an overall incidence of 1 in 50,000. Approximately 25% of cases are the result of a spontaneous mutation. HAE has three subtypes. Type I (85%) is characterized by low levels of C1 esterase inhibitor (C1 INH), type II (<15%) consists of normal but poor functioning levels of C1 INH, and type III (rare) has normal C1 INH levels.
and activity but probably involves another unidentified defect or gene mutation at the receptor level. Currently, bradykinin is thought to be the primary molecule responsible for angioedema in patients with HAE. Documented triggers include infection, stress, trauma, oral contraceptives, pregnancy, and menstruation.23

AAE comprises a heterogeneous group that includes drug-induced, idiopathic, and environmental agent–related angioedema and acquired C1 INH deficiency (ACID). ACID is characterized by a lack of inheritance and low-level or non-functional C1 INH. Drug-induced angioedema is most commonly caused by ACEIs.24 Up to 50% of those who still take an ACEI after an episode of angioedema will experience recurrent episodes. Discontinuation of the medication results in resolution of the symptoms in the majority of patients (within 24 to 48 hours). ACEIs block the degradation of kinins and thereby lead to elevated levels of bradykinin and other peptides. This results in vasodilation and tissue edema of the deeper layers of the skin, which is clinically manifested as angioedema.24

**PRESENTING SIGNS AND SYMPTOMS**

Angioedema has a brawny appearance and occurs when extravasation of fluid occurs at the subcutaneous and deep dermal layers of the skin. Patients with angioedema experience less pruritus than urticaria and often complain of a pain or burning sensation at affected sites. Angioedema also tends to involve the face, tongue, lips, and larynx but can occur in the mucosal layer of the gastrointestinal tract and genitalia in men. Involvement of the gastrointestinal tract can cause nausea, vomiting, diarrhea, and abdominal pain.

HAE is usually manifested in the second decade of life and appears either alone or with urticaria. Recurrent angioedema without urticaria later in life (e.g., middle age) may suggest some form of AAE, including ACID- and ACEI-induced angioedema (if undergoing ACEI therapy). Both HAE and ACEI-induced angioedema tend to have a predilection for the face, tongue, lips, oropharynx, and larynx. Patients with HAE may complain of a lump or tightness in the throat and progressive dyspnea. Physical examination may reveal hoarseness, inspiratory stridor, and rarely, urticaria. Prompt attention to airway management can be lifesaving. After stabilization, these patients need to be identified and referred to an allergist for further work-up and treatment.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

When angioedema is suggested by the history and physical examination, it is important to determine whether it is associated with other allergic findings, urticaria, a family history, or other medications (ACEIs). The differential diagnosis of angioedema is outlined in Box 106.4.

Patients suspected of having HAE should first have their complement 4 (C4) and complement 2 (C2) levels checked. As recommended by the consulting allergist or internist, other tests can include a CH50 (total complement activity) test, C1 INH test, or C1 functional assay. Additional screening tests may be considered to help rule out occult infection, hematologic or oncologic pathology, and rheumatologic or inflammatory disorders, which may aid the consultant in subsequent evaluation of these patients.

**TREATMENT**

The first priority in the management of patients with acute angioedema is to secure a patent airway if needed.22,23 Endotracheal intubation should be considered early in patients with progressive laryngeal edema. As soon as the patient is situated, intravenous access should be established, oxygen administered, and the patient placed on a monitor.

The majority of cases of angioedema are type I hypersensitivity reactions. If signs of airway compromise or hypoxia are present, epinephrine should be administered (0.3 to 0.5 mL of a 1 : 1000 dilution intramuscularly) and repeated every 5 minutes as needed. Nebulized racemic (or regular) epinephrine (0.5 mL of a 2.25% racpinephrine solution; multiple doses are acceptable in patients without intravenous access) can be a temporizing measure for pharyngeal and laryngeal edema before or in addition to parenteral administration of epinephrine. In patients with mild symptoms and no airway involvement, H1 and H2 antihistamines should be used first. Parenteral steroids (methylprednisolone, 125 mg intravenously) should be administered for moderate to severe attacks.

Epinephrine, antihistamines, and corticosteroids are generally ineffective in the treatment of HAE and ACEI-induced angioedema, although they are commonly given in the acute setting. The use of new drugs for acute HAE attacks and ACEI-induced angioedema is still in the formative stage. Plasma–derived C1 INH concentrate (Berinert, 20 U/kg intravenously, Cinryze, 1000 units intravenously) is currently available in the United States.93 Ecallantide, a kallikrein inhibitor (30 mg subcutaneously in adults), is another recent agent approved by the Food and Drug Administration for the treatment of acute HAE. Aminocaproic acid, tranexamic acid, and anabolic androgens (danazol, stanozolol) are often prescribed for HAE prophylaxis but may be considered for the treatment

---

**BOX 106.4 Differential Diagnosis of Angioedema**

- Cellulitis, erysipelas
- Acute contact dermatitis
- Crohn disease (of the mouth and lips)
- Dermatomyositis
- Venous disease (superior vena cava syndrome)
- Heart failure
- Photodermatitis
- Tumid discoid lupus erythematosus
- Meikerson-Rosenthal syndrome
- Ascher syndrome
- Facial lymphedema
- Renal disease

Anaphylaxis is a systemic reaction of rapid onset that involves multiple organ systems, principally the cutaneous, respiratory, cardiovascular, gastrointestinal, and central nervous systems. 

### ANAPHYLAXIS

**EPIEDMIOLOGY**

Anaphylaxis is a life-threatening systemic hypersensitivity reaction that is rapid in onset and usually precipitated within minutes of exposure to an allergen. Because of lack of data the true incidence of anaphylaxis is unknown, but recent evidence suggests that it is increasing and its incidence may be as high as 2%. Risk factors for anaphylaxis include atopy, higher socioeconomic status, northern locations, female sex, and route of allergen exposure. An individual with a history of asthma is more likely to experience a severe or fatal reaction.

**TRIGGERS**

Foods, predominantly peanuts, tree nuts, shellfish, fish, eggs, soy, and cow milk, are the most common cause of anaphylaxis and are responsible for up to 30% of all fatal cases. Insect stings, primarily by those belonging to the order Hymenoptera, are the second most common cause of anaphylaxis. They account for approximately 18.5% of anaphylactic cases. Medications are the third most common cause of anaphylaxis (13.7%). Although the β-lactams (penicillin) are commonly involved, several other drugs are known to cause anaphylaxis, including NSAIDs, aspirin, proamine, vancomycin, neuromuscular blocking agents, and newer biologic modifiers such as omalizumab, infliximab, and cetuximab.

Although the three groups just mentioned (foods, stings, and drugs) are responsible for the majority of anaphylactic reactions, other prominent triggers of anaphylaxis include latex, seminal fluid, transfusion products, allergen immunotherapy, contrast dye, methylmethacrylate (bone cement), and physical activity (exercise). Exercise-induced anaphylaxis is noteworthy because its pathophysiology is unknown. Some authorities suspect co-triggers, such as a specific food, drug, or recent high pollen exposure as the actual culprit. In approximately 20% of anaphylactic cases, no identifiable triggers are found, and the reaction is termed idiopathic anaphylaxis.

**PATHOPHYSIOLOGY**

Anaphylaxis is commonly an IgE-mediated type I hypersensitivity reaction, but it can also occur through other immunologic mechanisms or direct mast cell activation (formerly known as an anaphylactoid reaction). The resultant degranulation of mast cells and basophils causes the release of preformed mediators such as histamine, tryptase, carboxypeptidase A1, chymase, and tumor necrosis factor-α, as well as newly generated mediators such as leukotrienes, prostaglandins, cytokines, and platelet-activating factor. These vasoactive molecules together are believed to be responsible for the pathophysiology of anaphylaxis. Of these mediators, histamine is probably the most important. It mediates systemic vasodilation and increases vascular permeability, cardiac contractility, and glandular secretion. The leukotrienes, together with platelet-activating factor, contribute to vascular permeability and, in combination with prostaglandins (D2), cause bronchoconstriction.

**PRESENTING SIGNS AND SYMPTOMS**

Anaphylaxis is a systemic reaction of rapid onset that involves multiple organ systems, principally the cutaneous, respiratory, cardiovascular, gastrointestinal, and central nervous systems. 

Patients may initially experience warmth and tingling of the face, mouth, and chest, followed by nasal congestion, sneezing, and ocular itching and tearing. Urticaria, pruritus, and angioedema occur roughly 90% of the time. The majority of anaphylactic reactions become clinically evident within minutes after parenteral exposure (average of 5 to 30 minutes), with a longer latent time (2 hours) after the ingestion of a triggering agent. In general, the sooner the clinical syndrome is manifested after exposure to the allergen, the more severe the reaction. Most fatalities occur within the first 30 minutes after exposure. In the setting of shock, cutaneous symptoms may be absent as a result of compensatory vasoconstriction. Anaphylaxis may precipitate an acute coronary syndrome in what is known as cardiac anaphylaxis. More commonly in the elderly, the initial complaint may be abdominal pain and cramping.

In approximately 20% of patients, anaphylaxis may recur 1 to 72 hours after apparent clinical resolution of all signs and symptoms in what is called a biphasic reaction. There is currently no evidence or expert consensus on clinical predictors of the occurrence of a biphasic anaphylactic reaction, although it has been suggested that a biphasic reaction is rare in patients without hypotension and airway obstruction during the initial evaluation. Most authorities recommend an observation period (8 to 24 hours) after the initial manifestation to minimize the untoward effects of the biphasic reaction.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with mild symptoms who improved clinically after treatment and were observed for 4 to 6 hours in the ED can be discharged home with H1 antihistamines and a short course of steroids. If the patient was taking an ACEI, its use should be stopped. Replacement candidates include calcium channel blockers and thiazides. Angiotensin receptor blockers are deemed acceptable by some authorities because the risk for angioedema from these agents is considered acceptably low. Beta-blockers are not advised in the initial setting because of the theoretic risk of exacerbating the angioedema and potential antagonistic effects with epinephrine. Inpatient admission is warranted for those with moderate to severe symptoms who fail to display signs of resolution after 4 to 6 hours in the ED. In particular, patients with HAE should be managed in consultation with their primary physician or allergist. Most of these patients, especially those with a history of asthma and laryngeal involvement, warrant observation overnight in the hospital.
The clinical spectrum of anaphylaxis overlaps that of several other syndromes, especially those involving the skin and cardiorespiratory system (Box 106.6). Vasovagal reactions may mimic early anaphylaxis, although these patients usually have bradycardia, hypotension, diaphoresis, and pallor, as opposed to the tachycardia, hypotension, diaphoresis, and urticaria usually associated with anaphylaxis. Anaphylactic shock may also appear clinically indistinguishable from other forms of shock (distributive, septic, or cardiogenic). The acute onset and characteristic angioedematous urticarial rash favor the diagnosis of anaphylactic shock. Flushing syndromes also frequently mimic anaphylactic reactions. They may be associated with dry skin or diaphoresis and are the result of numerous different drugs, ingestants, and other physiologic syndromes.

Anaphylaxis is diagnosed clinically. The diagnosis is considered highly likely when any of three clinical criteria in Box 106.7 are met.35

Currently, histamine and tryptase are the only measurable markers of anaphylaxis in clinical laboratories.31 Histamine plasma levels become elevated approximately 10 minutes after the onset of symptoms and remain so for up to an hour. Peak levels of serum tryptase occur between 60 and 90 minutes and persist for as long as 6 hours. These markers must be determined within the time frames mentioned and may be helpful when it is uncertain whether anaphylaxis has occurred. It should be noted that food-induced anaphylaxis may not be accompanied by elevated levels of tryptase. Additional laboratory tests and imaging may be necessary to help rule out other disease processes.

**TREATMENT**

Early administration of epinephrine is the mainstay of treatment of anaphylaxis (Box 106.8). It should be administered quickly and preferably intramuscularly in the lateral aspect of the thigh (vastus lateralis). Epinephrine should be considered if anaphylaxis is suspected even when only one system (e.g., skin) is involved. Doses can be repeated every 5 to 10 minutes or more frequently as indicated clinically.27,35 Caution should be exercised in patients with risk factors for ischemic heart disease, although there are no absolute contraindications to epinephrine in those initially seen in anaphylactic shock.
BOX 106.7 Clinical Diagnosis of Anaphylaxis

Anaphylaxis is highly likely when any of the following three criteria are fulfilled:

1. Acute onset (minutes to hours) of an illness with cutaneous or mucosal involvement AND at least one of the following:
   a. Respiratory compromise (e.g., dyspnea, wheezing/bronchospasm, stridor, hypoxia)
   b. Reduced blood pressure or symptoms of end-organ dysfunction
2. Two or more of the following occurring rapidly after exposure to a probable allergen (minutes to several hours):
   a. Involvement of skin or mucosal tissue
   b. Respiratory compromise
   c. Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced blood pressure after exposure to a known allergen for that patient (age specific, less than 90 mm Hg, or 30% decline from baseline)

BOX 106.8 Treatment Options for Anaphylaxis

General
Two large-bore intravenous lines (intraosseous if unable to acquire intravenous access)
Placement of the patient on a monitor
Supplement oxygen (nasal canula, non-rebreather mask)
Consideration of a tourniquet—If anaphylaxis is due to an insect sting at the distal end of an extremity (blood pressure cuff inflated to approximately 20 mm Hg greater than systolic blood pressure), release every 10 minutes for 1 minute or when the symptoms resolve

Epinephrine
Intramuscular (subcutaneous acceptable)—1:1000; adult: 0.3 to 0.5 mL every 5 minutes as necessary, titrated to effect; pediatric: 0.01 mL/kg every 5 minutes as necessary, titrated to effect
Alternatively, EpiPen (0.3 mL) or EpiPen Jr (0.15 mL) can be administered into the anterolateral aspect of the thigh; removal of clothing unnecessary
Intravenous infusion—1:100,000; 0.1 mL of a 1:1000 dilution in 10 mL of normal saline (NS); 100 mcg, over a 10-minute period; equivalent to 10 mcg/min for a 10-minute period, titrated to effect; repeat as necessary; continuous hemodynamic monitoring required
Continuous infusion—1 mL of a 1:1000 dilution of epinephrine in 250 mL of 5% dextrose in water (D5W) results in a concentration of 4 mcg/mL; can be started at 1 mcg/min and increased to 4 mcg/min if needed
Pediatric continuous infusion—rate of 0.1 mcg/kg/min (up to 30 kg) advised, with increasing increments of 0.1 mcg/kg/min to a maximum of 1.5 mcg/kg/min

Intravenous infusion should be used only in patients who remain hypotensive and have failed to respond to multiple intramuscular injections. Inhaled epinephrine may be used as adjunctive therapy for laryngeal edema but should never replace the intramuscular or intravenous route (Fig. 106.5).

In conjunction with the administration of epinephrine, the patient should be placed in the supine position with the lower extremities elevated. Intravenous access should be established, supplemental oxygen administered, and the patient placed on a monitor. Patients with rapidly progressive respiratory insufficiency will benefit from early endotracheal intubation. Use of rapid-sequence intubation should be approached with great caution because of the potential for rapid deterioration of the oral and laryngeal edema. Plans for backup airway support and rescue airway devices, including a surgical airway, may be prudent.

Hypotension is treated aggressively with crystalloid infusion and colloid as indicated clinically. Caution should be taken in patients with a history of congestive heart failure. Patients with persistent hypotension despite appropriate doses of epinephrine and intravenous fluid resuscitation should be administered vasopressors drips (see Box 106.8).

H1 antihistamine (diphenhydramine) should be given to improve the itching and hives in patients with anaphylaxis. H2 antagonists (ranitidine, cimetidine) have a synergistic effect with H1 antihistamines and should be given because
they improve vascular permeability, flushing, gastric secretion, and mucus production in the airway. Antihistamines, however, should be considered second-line agents after epinephrine. Inhaled β-agonists (albuterol) can be administered for bronchospasm refractory to appropriate doses of epinephrine. Glucocorticosteroid provides no immediate benefit in the early treatment of possible anaphylaxis (see Anaphylaxis. ISORDERS to given adequately to epinephrine and intravenous fluids. A glucagon infusion should be strongly considered in these cases (see Box 106.8). Conversely, these patients may also demonstrate unopposed β-adrenergic effects after epinephrine administration and may require an alpha-blocker such as phentolamine.

**PATIENTS WITH ALLERGY TO INTRAVENOUS CONTRAST MEDIA**

Pretreatment with antihistamines and steroids significantly decreases the frequency and severity of anaphylactoid reactions in patients who have sustained a previous reaction to intravenous radiocontrast media. Each hospital has its own pretreatment protocols for clinical procedures; Box 106.9 reproduces one such protocol.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients who experience complete resolution of symptoms and were never hypotensive can potentially be discharged home. Although the time frame for biphasic reactions varies significantly, limited literature suggests that patients be observed in the ED for up to 8 hours. Oral H1 antihistamines such as diphenhydramine (50 mg every 6 hours for 72 hours) and H2 blockers such as ranitidine (150 mg every 12 hours for 72 hours) along with oral prednisone may prevent possible relapse. These patients should be instructed to return to the ED if they experience any recurrent symptoms consistent with their previous anaphylactic reaction.

All patients who have experienced an anaphylactic or significant allergic reaction should be prescribed at least two anti-β-blockers such as phentolamine.

**BOX 106.9 Standard Pharmacologic Treatment Protocol for Patients with a History of Radiocontrast-Induced Anaphylaxis**

- Prednisone, 50 mg PO given 13 hours, 7 hours, and 1 hour before the procedure
- Diphenhydramine, 50 mg IM given 1 hour before the procedure
- Consider giving an H2 antagonist, such as ranitidine, 300 mg PO as drops 3 hours before the procedure

Epi-Pens, one kept at the common residence and another in the purse or briefcase. In addition, patients should be taught how to self-administer it. Predisposed patients should be encouraged to wear a Medic-Alert bracelet or carry a wallet card identifying their hypersensitivity. Patients should also be referred to an allergist for possible skin testing and hyposensitization immunotherapy.

Hospital admission should be considered for patients who show slow clinical improvement, were hypotensive, and had upper airway involvement or persistent bronchospasm. Patients at risk for a biphasic reaction, such as those maintained on chronic beta-blocker therapy, may also be candidates for extended observation in the hospital.

Joint Disorders

Kathleen S. Schrank

**KEY POINTS**

- A white blood cell count higher than 50,000/mm³ is suggestive of a septic joint; however, lower counts do not rule out this diagnosis. If the index of clinical suspicion for a septic joint is high but the test results are nondiagnostic, the disorder should be treated as an infection.
- Severely painful acute monarticular arthritis, with or without fever, is highly likely to be a septic joint; it is an emergency requiring parenteral antibiotics and possible surgical intervention.
- Joint prostheses, diabetes, rheumatoid arthritis, concurrent infection, and age older than 80 years are significant risk factors for bacterial joint infections. Acute problems in a prosthetic joint merit immediate discussion with an orthopedic surgeon.
- A sexually active young adult with an inflamed, painful joint is considered to have gonococcal arthritis until proved otherwise and should be treated accordingly.
- Gout and pseudogout are crystal-induced arthritides that although benign, may cause significant pain and morbidity. The patient’s pain can be significantly improved by anesthetic and steroid injection after arthrocentesis.
- Overlying soft tissue infection may preclude arthrocentesis or warrant a different approach.
- Syncope may be a warning of high risk for sudden cardiac death in patients with systemic inflammatory arthritides.
- Cervical spine disease is common with rheumatoid arthritis and osteoarthritis and must be considered before any attempt at endotracheal intubation that involves forced flexion.
- Serious complications of arthritides are rare but may be life- or limb-threatening.

**ARTHRITIS**

**EPIEMIOLOGY**

An estimated 20 million people in the United States have osteoarthritis (OA), and 2 to 3 million have rheumatoid arthritis (RA). The total cost of medical care, lost work time, and disability for OA alone is estimated to run 2% of the gross national product. The most common cause of joint pain is OA, but the most crucial challenge is identification of a septic joint. Septic arthritis occurs in all age groups but is more common in children than in adults, and about 10% of patients with an acutely painful joint will be found to have infection.

**PATHOPHYSIOLOGY**

The structure of diarthrodial joints (the most common type) includes the synovium, synovial fluid, articular cartilage, intraarticular ligaments, joint capsule, and juxtaarticular subchondral bone. The delicate synovium provides oxygen and nutrients to cartilage and produces lubricants. Articular cartilage deforms under mechanical load to minimize stress and provides a smooth surface for joint motion with minimal friction. Causes of joint disorders (Box 107.1) often overlap. Cumulative microdamage and remodeling occur with use and aging. Mechanical or metabolic disturbances may lead to a secondary inflammatory response, or an inflamed structure (e.g., a tendon) may rupture. Arthrosis is due to a mechanical insult, whereas arthritis is due to inflammation of the synovium. With inflammation comes white blood cell (WBC) infiltration, release of cytokines (e.g., tumor necrosis factor-α [TNF-α], interleukins) and other inflammatory mediators, and proliferation of cells or tissue. Edema collects around the joint, which causes stiffness. With prolonged inflammation, erosion of bone and destruction of the joint eventually occur and can produce deformity and chronic disability.

In addition to bone, muscles, and joints, “joint” pain may derive from nerves, skin, or periarticular structures (ligaments, tendons, bursae, bone). The enthesis is the structural insertion of tendon or ligament into bone. Inflammatory enthesitis is prominent in the spondyloarthropathies, such as reactive arthritis.

**PRESENTING SIGNS AND SYMPTOMS**

The clinical findings can narrow the potential cause of a patient’s symptoms (Table 107.1). Initial assessment must determine whether the anatomic site of the problem is the joint and then a general category of the disease, either inflammatory (septic versus aseptic) or noninflammatory (mechanical). A red, hot, swollen, painful joint is the classic finding with septic and other inflammatory arthritides. Arthritis patients may also have serious nonarticular complications of their disease or its treatment.
The onset and pattern of pain are important to determine (Box 107.2). Mechanical pain is worse with use, rapidly relieved with rest, and often least in the morning. If present, morning stiffness resolves quickly. Rapid onset over a period of minutes suggests trauma, internal derangement, or a loose fragment in the joint. Inflammatory pain is often worse with use as well, but not so quickly relieved with rest, and is commonly associated with morning stiffness (short duration with OA, prolonged with RA). “Gelling” (stiffness and immobility) after sitting in one position occurs with either type. Widespread pain with stiffness is typically due to inflammatory arthritis or fibromyalgia. Subjective pain without joint findings on examination is termed arthralgia. If the patient has tried medications without relief, the dosage should be determined because inadequate dosing is common.

Although pain is usually the main concern of patients with joint disease, it is important to determine whether other associated symptoms (e.g., fever, rash, eye symptoms) or findings are present that can aid in the diagnosis. For example, examination of the skin may reveal the malar or butterfly facial rash associated with lupus, the pustular lesions of gonococcemia, or the subcutaneous nodules of RA and gout.

The musculoskeletal examination attempts to identify the exact site of the problem—joint versus bone, muscle, periarticular, or superficial skin pain. Particular joint involvement may aid in making the diagnosis (Box 107.3). True joint pain is usually diffuse on palpation and increases with active and passive motion. Periarticular inflammation (tendonitis, bursitis, cellulitis) is generally more focal, with pain reproduced specifically at the joint site. Particular joint involvement may be associated with the subcutaneous nodules of RA and gout.

### BOX 107.1 Initial Causes of Joint Disorders

**Mechanical**
- Loss of articular surface
- Trauma
- Microfractures, remodeling, arthrosis
- Congenital dysplasias

**Metabolic**
- Crystal deposition
- Osteoporosis
- Inherited storage diseases (e.g., Gaucher disease)
- Endocrinopathies (e.g., acromegaly, hyperparathyroidism)

contraction or passive stretching of the involved muscles or tendons and usually only toward one side.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Mechanical, inflammatory, or metabolic causes of arthritis may be present, and the whole picture must be considered in narrowing the lengthy differential diagnosis (Box 107.4). A new diagnosis of a specific type of inflammatory arthritis may not be possible in one visit, but recognition that the case is inflammatory is important for interim care. The severity of a patient’s discomfort will determine the urgency of analgesia, which may be initiated well before refining the list of possible diagnoses.

Early identification of septic arthritis is a top priority. An infected joint is especially likely to be present in patients with inflammatory, acute monarticular arthritis, with or without fever. The presence of another site of infection (skin, lungs, urine, heart) or a joint prosthesis increases the likelihood considerably. Moderate fever is typical with a septic joint, whereas low-grade fever may be present with any inflammatory, acute monarticular arthritis, with or without infection of another site of infection. The presence of another site of infection (skin, lungs, heart) or a joint prosthesis increases the likelihood considerably. Moderate fever is typical with a septic joint, whereas low-grade fever may be present with any inflammatory arthritis. Treatment (antibiotics and drainage) must be initiated empirically while awaiting culture results.

Infections in nearby sites (bursae, skin, periosteum) should be distinguishable by careful examination and radiologic studies; ultrasonography may be very helpful in looking for joint effusions. High fever, chills, and signs of sepsis should prompt fluid resuscitation as needed and studies to identify any additional site of infection.

Although patients usually have a history of trauma or very sudden monarticular pain, fractures may occasionally be surprises, especially in those with severe osteopenia or altered mentation (e.g., alcohol abuse, seizures), in whom trauma might not have been noticed.

Signs and symptoms may overlap, but crystals found on arthrocentesis are diagnostic of crystal-induced arthritis. The recent addition of a medication that can cause hyperuricemia may be a clue, but serum uric acid levels alone do not make or rule out the diagnosis of gout. Frequently, the patient has had multiple bouts of gout in the same joint, most commonly the great toe.

**DIAGNOSTIC STUDIES**

Blood tests are rarely diagnostic in patients with synovial disorders but may be ordered sparingly to assist in management decisions. A complete blood count (CBC) and basic chemistry profile will identify anemia, an elevated WBC count, and renal dysfunction (which affects selection of

- Axial: Seronegative spondyloarthropathies
DO NOT USE.

Medications). The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are nonspecific but useful markers of inflammation. Coagulation studies are needed only if a patient is taking anticoagulants or a bleeding disorder is suspected. Creatine phosphokinase is helpful if muscle pain or weakness is detected. If clinical assessment raises concern for other autoimmune or systemic diseases, additional screening for multiorgan involvement with urinalysis, liver enzymes, electrocardiogram, and chest films may help. Serologic testing (e.g., rheumatoid factor [RF], antinuclear antibody, and Lyme serology, depending on the clinical impression) is generally done in follow-up settings.

Plain radiographs are ordered if a fracture, foreign body, septic joint, or tumor is suspected. If the initial films show no fracture but suspicion remains, films repeated in 1 to 2 weeks may show callus formation or abnormal alignment. Radiographic findings may also assist in diagnosing the type of arthritis (Box 107.5), although they may remain normal early in the course. The presence of degenerative changes in a painful joint supports the clinical suspicion of OA as the cause, but such changes also become common with age, even in asymptomatic joints; conversely, a normal film does not rule out OA. Similarly, calcified fibrocartilage is often found in patients with calcium pyrophosphate deposition (CPPD) disease but is common in asymptomatic patients as well. Ultrasonography is useful in confirming joint effusion, especially in joints that are difficult to assess, such as the hip. Other modalities are rarely indicated in the emergency department (ED). Although magnetic resonance imaging (MRI) can distinguish synovitis from effusion and identify rotator cuff tears or be used to evaluate ligament trauma, emergency MRI or computed tomography (CT) is indicated only if a severe joint complication is strongly suspected or if axial skeletal pain merits evaluation for stenosis or metastatic disease.

Arthrocentesis with synovial fluid analysis is an important diagnostic and therapeutic procedure for joint disease (see the Tips and Tricks box and Box 107.6). It is the only reliable means to rule out a septic joint, and it is essential in acute monarthritis to look for joint infection, crystals, or hemorrhaging. Possible complications of arthrocentesis include introduction of infection into the joint space, hemorrhaging, and adverse reactions to medications. Arthrocentesis of prosthetic joints is best done with orthopedic consultation.

Normal synovial fluid is clear and yellow in appearance. In degenerative joint disease the fluid itself is normal and thus remains clear. Bloody fluid suggests hemorrhaging. Fat droplets may confirm a fracture. Turbid fluid is observed in

inflammatory conditions: gout, pseudogout, and septic, rheumatoid and seronegative arthritides (Table 107.2).

Crystal analysis is performed under compensated polarizing microscopy. In patients with acute gout, monosodium urate crystals are present inside neutrophils in fluid from the affected joint. The crystals are typically needle shaped and appear yellow when parallel to the compensator; this is negative birefringence. Sensitivity is at least 85%, and specificity for gout is 100%. In pseudogout, the crystals are positively birefringent (blue when parallel to the compensator), usually rhomboid shaped, and also phagocytized by neutrophils. Acute gouty arthritis may occasionally coexist with septic arthritis or pseudogout.

Glucose may be decreased relative to serum glucose in severe inflammatory disorders: down to less than 50% of the serum glucose level in septic arthritis and 50% to 75% in rheumatoid and seronegative arthritides. However, evidence suggests that chemistry studies on joint fluid should be discouraged because their results may be misleading or redundant.

BOX 107.6 Arthrocentesis

**Indications**
- Suspected septic arthritis
- Diagnosis of nontraumatic joint disease by synovial fluid analysis
- Diagnosis of ligamentous or bony injury by confirmation of blood in the joint
- Establishment of the existence of an intraarticular fracture by the presence of blood with fat globules in the joint
- Relief of pain accompanying acute hemarthrosis or a tense effusion
- Local instillation of medications
- Obtaining fluid for analysis (culture, cell count, crystal studies)

**Contraindications (Relative)**
- Infection in tissue overlying the site to be punctured
- Presence of bacteremia
- Coagulopathy
- Joint prosthesis (contact an orthopedic consultant)
- Uncooperative patient

Viscosity can be measured grossly in the laboratory and ED. Inflammation decreases the hyaluronate portion of synovial fluid, and thus viscosity decreases. When dropped from a syringe, normal synovial fluid makes a 5- to 10-cm string of fluid before dropping. With inflammation, the string of fluid will be shorter or the fluid may simply form droplets.
begin in 1 to 2 days, peaks at about 1 week, and lasts for 1 week to a few months, during which time compliance with adjunctive measures helps prevent recurrence. Although minimal evidence supports the concern, repeated steroid use traditionally raises concern over cartilage damage, so use in the same joint is limited to every 3 to 4 months. Long-acting local anesthetic may be added to the injection for same-day short-term relief.8,9 If suspicion for an infected joint is high, intravenous antibiotics are administered after appropriate material is sent for culture (see discussion later under “Septic Arthritis”).

Follow-up, Next Steps in Care, and Patient Education

Serious situations may warrant admission (Box 107.7). Patients with joint infections require admission and early consultation with an orthopedic surgeon or rheumatologist. Most other patients will be discharged home with an analgesic and general treatment measures to relieve pain. Full-dose acetaminophen (650 to 1000 mg four times daily) may be adequate (especially if a history such as gastrointestinal [GI] bleeding, heart failure, or renal failure makes use of an NSAID risky), or an NSAID may be selected based on low cost and safety profile (e.g., celecoxib may be safer for the stomach). The NSAID is begun at a high dose (e.g., ibuprofen, 600 to 800 mg three times daily), continued for at least 2 to 3 days (or with inflammatory arthritis, for at least a few days after the pain stops), and then may be continued as needed. The patient is advised to take NSAIDs with food, especially with a history of stomach upset, and cotreatment with a stomach-protective drug (H2 blocker, proton pump inhibitor, or sucralfate [Carafate]) should be considered. Nonresponders
ergonomic advice may assist patients with pain related to repetitive motions when the activity is unavoidable.

Appropriate lifestyle recommendations for patients with chronic arthritis are to stay as active as possible with daily activities and reasonable exercise programs. Physical and occupational therapy" may contribute greatly to improved quality of life and ability to maintain independence in self-care but are usually arranged by the continuity physician. Initial range-of-motion (ROM) and later strengthening and aerobic exercise regimens are recommended; swimming pool exercise programs are quite helpful. Obese patients with lower extremity arthritis should be educated about the importance of weight reduction.

Follow-up care includes referral to a primary care physician for most patients. Rheumatology referral is recommended for patients with clinical suspicion of new inflammatory or autoimmune arthritides such as RA or for patients not improving despite adequate general care. Chronic severe pain with significant disability merits orthopedic referral. Patient education is vital for achieving an optimal outcome (see the Patient Teaching Tips box).

**RHEUMATOID ARTHRITIS**

**Epidemiology**

RA is the most common inflammatory arthritis, with about 0.8% of the world’s population afflicted, and it has a 3:1 female preponderance. It begins most commonly in the 40s. Overall, life expectancy is only modestly reduced, but quality of life may be significantly impaired. The majority of patients experience chronic remitting but overall progressive disease, including about 10% with an aggressive, severely destructive pattern and 15% to 30% with intermittent remissions lasting up to 1 year; about 15% experience a long-lasting remission with excellent function.13

**Pathophysiology**

RA is a systemic inflammatory autoimmune disease that primarily targets the synovium and transforms it into hyperplastic inflamed and thickened tissue that proliferates into a pannus. The pannus is unique to RA, where it grows over the articular cartilage, erodes into bone, and causes destruction and deformity. Synovial fluid contains abundant neutrophils, cytokines, proteolytic enzymes, prostaglandins, and leukotrienes. The etiology of RA remains unknown, but it is probably caused by a combination of environmental factors and genetic susceptibility, with several contributing genes, particularly the class II major histocompatibility complex. An ongoing and uncontrollable immune response is elicited, perhaps against an autoantigen. RFs are IgM or IgG antibodies synthesized in the synovium that form immune complexes with IgG in the blood or joints.

**Presenting Signs and Symptoms**

RA is characterized by symmetric polyarthritis persisting for more than 6 weeks, prolonged morning stiffness (>30 minutes),...
and systemic symptoms of fatigue, malaise, and weight loss. Diagnostic criteria are listed in Table 107.3. Arthritis typically starts in the small joints (metacarpophalangeal [MCP], metatarsophalangeal [MTP], and proximal interphalangeal [PIP] joints of the hands and feet but not the distal interphalangeal [DIP] joints) and later affects larger extremity joints. Migratory polyarthritis occurs, and the symptoms may wax and wane. The onset of RA is typically insidious but can be abrupt. Cervical spine involvement is prevalent, although the rest of the spine is usually spared. RA increases the risk for a septic joint or tendon rupture, and temporomandibular joint (TMF) problems are common.

Examination in the early stages usually finds tenderness, swelling, and limited ROM in at least three joints, especially in the hands and feet. Warmth and erythema are uncommon. Palpation may reveal loss of the normal contour across joints (especially the MCP joints) because of pannus. Rheumatoid nodules are found in 20% of patients and can appear anywhere but especially over bony prominences, pressure points, and tendon sheaths. These nodules may be fixed or mobile with a rubbery or granular texture and are sometimes indistinguishable from gouty tophi. They are not a serious problem unless they occur in the vocal cords or cardiac conduction tissue. Typical later joint deformities are radial deviation at the wrist (usually the earliest deformity), ulnar deviation at the MCP joints (the most characteristic deformity of RA), swan neck or boutonnière deformities of the fingers, cock-up toes, loss of arches, and hallux valgus.

Extraarticular manifestations are common. Acutely life-threatening complications are rare but disastrous. Patients may also have serious complications of chronic treatment, particularly with infections from immunosuppression.

Differential Diagnosis and Medical Decision Making

Identification of septic arthritis is the top priority given its risk for rapid joint destruction or systemic infection. Patients with known RA are at significantly increased risk, and clinical findings may be more subtle because of their drug regimens. Joint fluid analysis is essential. Systemic infections may seed a joint or induce an immunologic arthritis; mild systemic symptoms may be difficult to distinguish from those of exacerbation of RA.

OA is the most common consideration in the differential diagnosis, but its pattern of joint involvement (especially in the hands) and minimal to absent systemic symptoms distinguish it from RA. Self-limited arthritic syndromes (e.g., viral infections, Lyme disease) can be difficult to distinguish clinically from the initial findings in patients with RA, and thus the RA criteria require persistence of the joint symptoms for longer than 6 weeks. The usual time from onset to diagnosis of RA is 6 to 12 months, but joint damage occurs early, with 30% of patients exhibiting bone erosion at time of diagnosis.

Studies may assist in the differential diagnosis. RA typically produces a mild normochromic normocytic anemia and thrombocytosis but normal WBC count (unless infected or Felty syndrome is present), an ESR of 30 to 60 mm/hr, and an elevated CRP level. On plain films, RA is characteristically associated with joint space narrowing (especially in the MCP, PIP, and wrist joints), marginal bony erosions, periarticular osteopenia, and soft tissue swelling (Fig. 107.1). Joint destruction (e.g., femoral head protruding through the acetabulum) occurs late.

Serologic testing (RF IgM or anti–citrullinated protein antibody [ACPA]) for a new diagnosis is generally best done in...

ACPA, Anti–citrullinated protein antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor IgM.

*Score-based algorithm: Add the scores of categories A to D; a score of 6 or higher of a total of 10 is needed for to classify a patient as having definite RA.
The majority of RA patients will be discharged (see Box 107.7). Immunosuppressed patients warrant high suspicion for infection and a low threshold for admission. Follow-up visits with either a primary care physician or rheumatologist (if a new diagnosis or not responding to treatment) are essential. Chronic severe joint dysfunction merits orthopedic referral for potential surgical intervention (joint replacement, arthrodesis, synovectomy).

Disease-modifying antirheumatic drugs (DMARDS) are essential for all RA patients to prevent joint damage and are now initiated as early as possible after diagnosis (but not in the ED). The mainstay remains methotrexate, alone or in combination. Leflunomide (an immunomodulatory drug) and sulfasalazine are alternatives. Exciting new and effective biologic agents include anticytokine therapies such as etanercept, anakinra, abatacept, and rituximab.

OSTEOARTHRITIS

EPIDEMIOLOGY

OA is the most common cause of joint pain and frequently leads to chronic pain and disability. In the United States, symptomatic knee OA occurs in 6% of persons older than 30 years and hip OA in 3%. About one third of adults aged 25 to 74 years have radiographic evidence of OA in at least one joint group, most commonly the hands and then the feet and knees. Prevalence increases considerably with age, and OA is a major cause of disability, lost work time, and early retirement. Before the age of 50, prevalence in most joints is higher in men, but at older ages women are more often affected in the hands, feet, and knees.

Other risk factors include obesity, trauma, family history, and occupations involving repetitive knee or hip bending and lifting (e.g., farmers, dockworkers). The role of aggressive exercise remains unclear, although moderate running appears to be low risk. High-intensity contact sports and those involving repetitive joint impact and twisting are higher-risk categories.

PATHOPHYSIOLOGY

OA is a disease of articular cartilage and subchondral bone that is characterized by patchy loss of cartilage, overgrowth of bone at the joint margins (osteoophytes are hallmarks of OA), hypertrophy of subchondral bone, fibrosis in the joint capsule, loss of joint space, and mild inflammation of the synovium. Loss of cartilage allows the underlying bones to rub together, which produces pain, swelling, and limited ROM. The primary process is mechanical, not inflammatory, but past views of OA as being entirely mechanical (hence names used in the past such as degenerative joint disease and osteoarthritis) are inaccurate because recent evidence shows considerably more synovial inflammation.

TREATMENT

General measures (analgesics, ice, rest, joint support) are needed for relief of pain. NSAIDs are the mainstay of initial symptomatic treatment, although these drugs do not modify the overall course. Unless contraindicated, the maximal dose of an NSAID is administered for a minimum 2-week trial. Concomitant use of an additional analgesic is often helpful.

Low-dose corticosteroids (prednisone, 5 to 10 mg daily) are often tremendously helpful for rapid relief of symptoms but are generally initiated after failure of general measures and an adequate NSAID trial. In RA, corticosteroids are usually superimposed on other treatment regimens. If the patient has only one or two very problematic joints that are clearly not infected, intraarticular corticosteroids can produce rapid improvement lasting for several weeks to months.

Fig. 107.1 Ulnar deviation in a patient with rheumatoid arthritis. Severe ulnar deviation with extensive erosions is present at the metacarpophalangeal joints. Pancompartmental bony ankylosis and erosion are also seen in the wrist. (From Harris E, editor. Kelley’s textbook of rheumatology. 7th ed. Philadelphia: Saunders; 2005.)
than was previously considered. Its pathogenesis involves chronic mechanical microdamage, disturbed chondrocyte regulation of the synthesis and degradation of cartilage matrix, genetic factors, and inflammatory pathways. Local mechanical factors (malalignment, laxity, proprioception) contribute in specific joints.

Most cases are classified as idiopathic or primary. Secondary osteoarthritis may result from congenital or developmental diseases, trauma, deposition diseases (calcium, hemochromatosis), neuropathic arthropathy, or endocrinopathies (e.g., acromegaly, hyperparathyroidism).

**PRESENTING SIGNS AND SYMPTOMS**

OA most commonly affects the knees, hips, spine, fingers (especially the DIP joints and first carpometacarpal joint), and toes (especially the MTP joints). ED visits are usually prompted by significant pain in a large joint (knees or hips) that is often associated with an acute but minor injury. Neck or back pain is also common. Patients typically report a gradual onset of pain and stiffness in one or a few joints with limited ROM. Locking or instability of the knee is common, as is joint effusion. Baseline pain is mild to moderate, worse with use, and rapidly better with rest, and the symptoms are worse in damp, cool weather.

On examination, disease is found to be limited to the symptomatic joints. Joint tenderness, bone enlargement, and crepitus on joint motion are common findings. Heberden nodes (hard nodules on the dorsal aspect of the DIP joints) are commonly seen in older women with OA. Malalignment is found in about half of knees with OA, typically with a varus (bowleg) deformity and often with instability on excess ROM. Joints may be mildly warm, especially if an effusion is present, but not dramatically inflamed. Late in the disease course, significant joint disability is evident (Fig. 107.2).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Although OA is a polyarthritis, it most commonly affects just a few joints in each patient. Prominent general systemic symptoms point to another diagnosis, such as RA or fibromyalgia, whereas active involvement of other organs suggests other autoimmune arthritides. Patients are prone to coexisting pseudogout in the knee, or gout may develop. A red, hot swollen joint is probably infected or acute crystal-induced arthritis.

If ordered, laboratory results are generally normal. Joint fluid is usually noninflammatory, with a WBC count lower than 2000/mm³; inflammatory fluid may occur in OA but more often suggests gout or infection. Radiologic results must be correlated with the clinical picture. In asymptomatic patients older than 40 years, radiographic studies often show degenerative joint changes, but a label of OA would be incorrect. The classic changes with OA are degenerative with marginal osteophyte formation, subchondral bony sclerosis, and asymmetric joint space narrowing. Later, subchondral cysts with sclerotic walls form, and bone remodeling distorts the ends of bones. Bone demineralization and marginal erosions suggest an inflammatory arthritis such as RA.

**TREATMENT**

Initial attempts at pain relief in the ED include analgesics, ice, and support in a position of comfort. Acetaminophen or ibuprofen may be adequate. If a patient has already adequately tried and failed to obtain relief with these medications, tramadol or narcotic analgesics should be considered. If a significant effusion is causing pain and disability, removal of fluid provides considerable relief. Intraarticular corticosteroids are also effective, especially in the knee or MCP joints, with pain relief lasting weeks to months. Intraarticular hyaluronic acid injections have been used in the knee, but their efficacy is limited.

**FOLLOW-UP, NEXT STEPS IN CARE, AND ADMISSION**

As with other arthritides, the vast majority of patients with OA are discharged home with recommendations for primary care follow-up, whereas those with known or strongly suspected joint infection are treated and admitted to the hospital. Several options are available for discharge analgesia. Patients with mild symptoms may need only general care measures. Acetaminophen and NSAIDs are the first-line choices. In studies both have been shown to be effective in reducing pain, although NSAIDs or celecoxib is modestly better. However, acetaminophen has less risk for side effects and thus remains a good first choice. Effective additions or alternatives include tramadol or short-term use of narcotics.
Topical NSAIDs (not salicylates) are considered core treatment of OA of the knee or hands, and topical capsaicin is considered adjunctive to core treatment of these joints; strong evidence supports their benefits. Glucosamine sulfate (1500 mg/day) and chondroitin sulfate (1200 mg/day) may shift cartilage metabolism toward a positive balance and are widely popular among patients, but the overall evidence to date shows limited efficacy; these over-the-counter preparations may vary considerably in composition.

General care measures and patient education are also important (see the Patient Teaching Tips box presented earlier and Box 107.8). Evidence supports the benefit of exercise regimens and weight loss in patients with knee arthritis. Correction of knee malalignment with a neoprene sleeve, valgus brace, orthotics, or a combination of such devices is beneficial. Evidence on the benefit of acupuncture is mixed.

Surgical interventions are useful in selected situations; knee arthroscopy is beneficial if cartilage flaps, loose bodies, or meniscal disruption is causing mechanical locking or instability. Total joint replacement for knee or hip OA often dramatically improves severe refractory pain and disability, particularly if the patient has a relatively low body mass index. Chondrocyte transplantation is an exciting intervention for future care.

### REACTIVE ARTHRITIS

#### EPIDEMIOLOGY

Reactive arthritides are seronegative spondyloarthropathies that are much less common than OA and RA; however, identification is important to guide management. Most are self-limited illnesses, but persistent and severe disease develops in a minority of patients (particularly those with acquired immunodeficiency syndrome). Prevalence parallels that of the human leukocyte antigen (HLA) B27 genes in different populations. In the United States, 6% to 14% of Caucasians have HLA-B27, as do 2% to 3% of African Americans. The peak onset is during the third decade of life. Reactive arthritis has a 5:1 to 6:1 male preponderance, but cases in women may be underdiagnosed—women tend to have milder symptoms, and their genitourinary (GU) manifestations may be occult. The incidence of reactive arthritis is estimated to be 3 to 6 cases per year per 100,000 males younger than 50 years.

#### PATHOPHYSIOLOGY

In reactive arthritides, a sterile inflammatory arthropathy arises, commonly after a primary infection elsewhere in the body. Onset typically occurs 1 to 4 weeks after a diarrheal or GU infection, once the triggering infectious illness is over. Enteric pathogens include Shigella, Yersinia, Salmonella, Campylobacter, and Clostridium difficile. Sexually transmitted pathogens include Chlamydia (mainly Chlamydia trachomatis), Ureaplasma urealyticum, and human immunodeficiency virus (HIV). Presumably, microbial material or products are disseminated to the joints and extraarticular structures and trigger an inflammatory response consisting of mononuclear infiltration into the joints and entheses, synovial effusions, and inflammatory mediators. Most patients carry HLA-B27 genes. In many, the inciting infection is not identifiable.

Inflammation of the entheses, eyes, and mucosal surfaces is a distinctive feature of reactive arthritis. The illness tends to be self-limited over several months, but relapses occur in about one third of patients. HIV-associated disease is often severe and disabling.

### BOX 107.8 General Treatment Measures for Chronic Arthritis

**Patient Education**
Nature and usual course of the disease
Exacerbating and relieving factors
Avoidance of repetitive injuries, impacts
Arthritis self-help course available from the Arthritis Foundation (www.arthritis.org)

**Painful Joint**
Analgesics (take a bedtime dose if early morning pain), oral and/or topical
Acute exacerbations:
- Rest, ice, compression, elevation
- Temporary limitation of range of motion and forceful use
Correction of malalignment—joint sleeve or brace, orthotics
Chronic pain—trials with ice, heat, in-water therapy
Unloading joint stress with a cane or crutch (contralateral to the affected leg)

**Physical Therapy**
Relief of pain and muscle spasm (massage, heat, ultrasound, electrical stimulation therapy, physical maneuvers)
Improvement in and preservation of range of motion
Strengthening (general or surrounding a specific joint)
Progressive individualized exercise regimen
General conditioning

**Occupational Therapy**
Improved activities of daily living
Assist devices
Temporary splinting
Protective techniques
Energy conservation skills

**Lifestyle**
Weight loss program
Adequate nutrition and calcium intake
Range-of-motion preservation
Exercise program with low-impact aerobic conditioning
Evaluation of the home for fall prevention, improved functionality
Well-cushioned shoes or orthotics

**Acupuncture**
Role unclear; efficacy not well supported by available evidence; appears beneficial for knee pain

**Glucosamine and Chondroitin**
Role unclear; efficacy not well supported by available evidence
CLASSICALLY OR PALMS PUSTULAR ACHILLES PAPULOSQUAMOUS BLENORRHAGICUM—PAINLESS SOLES, THE SIMILAR TO PLANTAR AND ON 

TRIAD THAT WAS FORMERLY NAMED REITER SYNDROME INCLUDES ACUTE WAVES, OR AORTIC REGURGITATION.

With conduction blocks, nonspecific ST-segment changes, Q

UVEITIS, AND CARDBONE INVOLVEMENT (IN ABOUT 10% OF PATIENTS)

PAIN OR ABOUT RECENT DIARRHEAL OR GU INFECTIONS.

Cases of reactive arthritis seen in the ED are likely to be a

NEW DIAGNOSIS. TYPICALLY, THE PATIENT REPORTS ONE OR A FEW SITES

OF ACUTE JOINT PAIN, OFTEN ASYMPTOMATIC WITH SEQUENTIAL

ONSET. COMMON SITES INCLUDE LARGE JOINTS (ONE OR BOTH ANKLES,

WRISTS, KNEES) AND SMALL JOINTS IN THE FEET; THE UPPER EXTREMITIES MAY BE INVOLVED LATER. FEVER (UP TO 102.2°F [39°C]),

CONSTITUTIONAL SYMPTOMS (FATIGUE, MALAISE, WEIGHT LOSS), AND

MUCOSAL PROBLEMS ARE COMMON FINDINGS (BOX 107.9). LOW BACK PAIN, BACK STIFFNESS, OR SACROILIITIS OCCURS IN HALF THE

PATIENTS.31 THE INVOLVED JOINTS ARE OFTEN INFILTRATED. THE CLASSIC TRIAD THAT WAS FORMERLY NAMED REITER SYNDROME INCLUDES ACUTE PERIPHERAL ARTHRITIS (ASYMMETRIC, OLIGOARTICULAR, ADDITIVE), CONJUNCTIVITIS (MILD, USUALLY SEVERAL DAYS BEFORE THE APPEARANCE OF JOINT PAIN), AND NONGONOCOCCAL URETHRITIS OR CERVICITIS (GENERALLY MILD, PRECEDES THE JOINT PAIN).

Most patients do not manifest the full triad. Some may not volunteer information about other symptoms before their joint pain or about recent diarrheal or GU infections.

Later complications can include ankylosing spondylitis, uveitis, and cardiac involvement (in about 10% of patients) with conduction blocks, nonspecific ST-segment changes, Q waves, or aortic regurgitation.

With an acute hot joint, infection (especially gonococcal) must be ruled out. Active infection elsewhere (especially the GI and GU tracts) must also be considered. Reactive arthritis should be distinguished from seronegative RA, crystal-induced arthritis, sarcoidosis, acute rheumatic fever, psoriatic arthritis, and erythema nodosum. A carefully constructed clinical picture will usually distinguish reactive arthritis, but this may not easily be done in the ED.

Given the frequent finding of fever, acute arthritis, and involvement of mucosal surfaces in patients with reactive arthritis, laboratory studies are appropriate (CBC, chemistries, liver enzymes, urinalysis, ESR, arthrocentesis, joint fluid cultures, and usually blood cultures). In reactive arthritis, a modest increase in WBCs, platelets, and ESR is expected, and mild anemia is common. Active urethral or GI infection should be considered, and tests for Chlamydia and gonorrhea are appropriate if the patient has had any recent GU symptoms. If the precipitating infection was dysenteric, stool should be sent for culture. Serologic and HLA studies are not done in the ED.

**PRESENTING SIGNS AND SYMPTOMS**

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

**BOX 107.9 CLASSIC SIGNS OF REACTIVE ARTHRITIS (FORMERLY KNOWN AS REITER SYNDROME)**

**TREATMENT**

Full-dose NSAIDs are the mainstay of therapy for reactive arthritis—a good response is typical.32 General care measures are also appropriate (see earlier), especially encouragement of continuing exercise. Systemic corticosteroid therapy is not generally indicated, but intraarticular glucocorticoids may help in alleviating persistently problematic joints after ruling out infection. Second-line medications for nonresponders include sulfasalazine or methotrexate. Experience with anti-TNF agents is limited but promising.

Antibiotic treatment of Chlamydia is appropriate if the initial infection was untreated or is found on testing. Empiric administration of an antibiotic to patients with a previous history of GI infection is not useful unless current stool cultures show persistence of a pathogenic trigger.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Most patients with reactive arthritis can be discharged home with primary care follow-up, but admission is indicated if the patient is febrile or if active joint infection is likely. Referral to ophthalmology is advised if uveitis is suspected.

**SEPTIC ARTHRITIS**

**EPIDEMIOLOGY**

The incidence (expressed per 100,000 per year) of septic arthritis varies between 2 and 5 in the general population, 5 and 12 in children, 28 and 38 in patients with RA, and 40 and 68 in patients with joint prostheses. Males are usually affected more commonly than females, although with underlying RA, females are affected more often. About 10% of patients with acutely painful joints will have septic arthritis.1

The organisms causing bacterial arthritis depend on the epidemiologic circumstances (Table 107.4). For example, monarthritis of a prosthetic joint is probably due to *Staphylococcus* species, whereas a migratory arthritis in a sexually active woman is probably due to disseminated gonococcal infection. Rarely, the cause may be fungal, protozoal, or mycobacterial, particularly in immunosuppressed patients. Viral joint infections are not considered part of the “septic” category.

Major risk factors for septic arthritis in adults include age older than 80 years, diabetes mellitus, RA, prosthetic joint or recent joint surgery, skin infection or ulceration, alcoholism,
Septic arthritis is generally manifested acutely as a “hot joint”—with joint pain, swelling, erythema, limited and painful ROM, and tenderness. Septic arthritis is usually monarticular, but about 10% of patients have polyarticular involvement (of those, >50% have underlying RA). The knee is the most common site, followed by the hip, wrist, ankle, and shoulder. Fever is common, though often absent in the elderly, and patients frequently have another site of recent infection.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis for septic arthritis is focused on other inflammatory diagnoses. Although low-grade fever is common with many types of inflammatory arthritis, higher fevers are more commonly associated with a septic joint, and the physician must rule out a septic joint with joint fluid analysis (see Table 107.2).

A history of gout makes a recurrent gout attack more likely. However, patients with gout are more susceptible to septic arthritis. Gouty arthritis is more likely than septic arthritis to be manifested in a polyarticular fashion. In general, a septic joint will be redder and warmer, whereas a gouty joint will have more fluid.

Unfortunately, laboratory tests, including synovial fluid analysis, do not diagnose or rule out septic arthritis with accuracy. Therefore, if suspicion for septic arthritis is high in the setting of negative testing, the emergency physician should not hesitate to treat for infection while awaiting the results of bacterial culture. Imaging studies are indicated when trauma, bone infection, malignancy, or a foreign body is suspected and are recommended before arthrocentesis. Ultrasonography may assist in identification of joint effusion.

**TREATMENT**

Pain management should be initiated early. After appropriate material for culture is obtained, parenteral antibiotics should be selected to treat the most likely pathogens (see Table 107.4). Another reasonable approach is to treat according to Gram stain results (for gram-positive cocci, start vancomycin; for gram-negative organisms, start ceftriaxone or cefotaxime).

If the Gram stain is negative, vancomycin is reasonable for an immunocompetent host and vancomycin plus ceftriaxone (or cefotaxime) for an immunosuppressed individual, injection immunocompetent host and vancomycin plus ceftriaxone (or cefotaxime) for an immunosuppressed individual, injection

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Hospital admission is needed, along with orthopedic consultation and repeated arthrocentesis if fluid reaccumulates. The patient should be advised about the probable diagnosis and plan of care.

---

**PRESENTING SIGNS AND SYMPTOMS**

Bacteria can infect the joint via hematogenous spread, direct inoculation (arthrocentesis, trauma, surgery), or contiguous contact (cellulitis, bursitis, tenosynovitis). Any microorganisms, including bacteria, fungi, and protozoa, may invade joints; however, the overwhelming majority of cases (90%) are caused by the pyogenic bacteria *Staphylococcus* and *Streptococcus*. Once the pathogen penetrates the joint space, it initiates a series of inflammatory reactions that may lead to joint destruction and permanent damage. Microorganisms or their products (or both) activate the release of proinflammatory cytokines, such as TNF-α and interleukin-1, and proteolytic enzymes, such as metalloproteinases and other collagendegrading enzymes. These proteins induce synovial membrane proliferation, granulation tissue, neovascularization, and infiltration by polymorphonuclear cells and may result, if untreated, in cartilage and bone destruction. The articular damage may progress even after eradication of microorganisms because persistence of bacterial antigens and metalloproteinases within the joint will continue to promote an inflammatory response.
GOUT AND PSEUDOGOUT

EPIDEMIOLOGY

The incidence of gout ranges from 1% to 15% in the general population and increases with age and with elevations in serum urate. In adults, serum urate levels correlate strongly with serum creatinine levels, body weight, height, age, blood pressure, and alcohol intake. Acute gout is much more common in men (peak age at onset between the fourth and sixth decades) but tends to occur at older ages in women (sixth to eighth decades). Radiography and autopsy studies have found the incidence of pseudogout to be 15% at age 65 and 50% at age 85.

PATHOPHYSIOLOGY

Gout and pseudogout are characterized by crystal deposition in joints with recurring attacks of acute inflammatory arthritis, as well as chronic arthropathy.

Although acute gout never develops in most hyperuricemic individuals, all patients with gouty arthritis have hyperuricemia at some point. Microscopic tophaceous deposits of urate crystals develop in synovial membranes, but deposits alone are asymptomatic. Abrupt increases and decreases in serum urate levels may promote the release of free urate crystals from deposits, which have considerable proinflammatory potential because of their ability to activate synovial epithelial cells and promote the ingress of leukocytes into the joint, which triggers multiple inflammatory cascades. Precipitants include initiation of diuretics and other drugs that inhibit the excretion of uric acid (including aspirin), alcohol use, initiation of urate-lowering drugs, starvation, and tumor lysis. Repetitive joint microtrauma may produce locally increased urate concentrations, which perhaps explains the predilection for the first MTP joint.

An acute gouty attack is spontaneously self-limited (usually lasting 7 to 10 days) and probably mediated by an altered balance between proinflammatory and antiinflammatory mediators in the joint. Low-grade synovitis may persist in affected joints. Inflammation, especially with untreated disease, can lead to chronic synovial proliferation, cartilage loss, and bone erosion. Tophi commonly develop in osteoarthritic interphalangeal joints, thus suggesting a role of connective tissue matrix structure and turnover in urate crystal deposition.

Calcium-containing crystals in the pericellular matrix of cartilage are often deposited in the form of CPPD and therefore lead to a disorder termed chondrocalcinosis, pyrophosphate arthropathy, CPPD crystal deposition disease, or when associated with acute arthritis, pseudogout. Precipitation of CPPD crystals in connective tissue is most often asymptomatic. Acute attacks are generally self-limited and often triggered by trauma, surgery, or severe medical illness.

PRESENTING SIGNS AND SYMPTOMS

Acute inflammatory joint pain, swelling, erythema, and tenderness with painful limited ROM are typical. Inflammatory signs often extend beyond the involved joint and resemble cellulitis. Classically, acute gout affects the first MTP joint, but more than 50% of pseudogout attacks affect the knee. Eighty percent of first gouty attacks are monarticular. Low-grade fever is common in both diagnoses, and a previous history of the joint disease is common.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

A known history of gout, typical precipitants, or location in the great toe suggests gout. Chondrocalcinosis (radiographic evidence of calcification in hyaline cartilage, fibrocartilage, or both) is common in pseudogout; though highly suggestive of the diagnosis, it is neither absolutely specific nor universal. Leukocytosis with a left shift and an elevated ESR may be present but are more common in pseudogout than gout. An elevated uric acid level may or may not be found in acute gout and is nondiagnostic by itself. Normal to low levels are reported in 12% to 43% of patients with acute gout attacks. The pattern of symptoms in chronic pseudogout is often similar to OA and may sometimes mimic RA. A significant minority of patients have coexisting arthritides.

Evaluation for septic arthritis is the diagnostic priority in the ED. Joint aspiration with evaluation of synovial fluid for acute inflammation, crystals, or evidence of infection is necessary, and fluid must be sent for Gram stain and culture. Urate crystals inside neutrophils diagnose gout; phagocytosed CPPD crystals are seen in pseudogout. Some patients have concurrent gout and pseudogout, with both types of crystals being found. Coexistence of crystalline and infectious arthritis in the same joint is well reported. If joint fluid analysis cannot be done, a clinical diagnosis may be made from historical and clinical data, but specificity is reduced (Table 107.5).

TREATMENT

Although acute attacks will resolve spontaneously, antiinflammatory medications are essential for more rapid relief of pain. Even though colchicine has traditionally been used for the acute treatment of gout, rheumatologists prefer NSAIDs (other than aspirin), oral prednisone (30 to 50 mg/day for 5 to 7 days), or intraarticular corticosteroids. Low-dose oral colchicine (1.2 mg and then 0.6 mg in 1 hour or 0.5 mg every 8 hours for 1 day) is safe and effective and avoids the diarrhea and vomiting that were common with higher-dose regimens. Pseudogout is treated with NSAIDs or intraarticular cortisone (or both); effective prevention is often achieved with low-dose colchicines or NSAIDs.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Drugs that lower uric acid production (e.g., allopurinol, febuxostat) or enhance excretion (e.g., probenecid) may be

- Intermediate probability: 4-8 points
- Low probability: <4 points

Arthritis
Presence or absence of the following:
- Cardinal signs of inflammation (pain, tenderness, heat, erythema, swelling)
- Functional impairment and ability to bear weight
- Constitutional and systemic symptoms
- Traumatic injury
- Risk factors for joint space infection
- Risk factors for adverse effects of the planned treatment regimen
Clearly identify the specific anatomic sites of tenderness, swelling, and erythema
Assess and document the following:
- Characteristics of pain (PQRST mnemonic)
- Full set of vital signs
- Approximate range of motion of the affected joints; level of activity
- Witnessed functional impairment, weight bearing, and gait
- Distal neurovascular status
- Patient consent, procedure note, results of a tap if arthrocentesis is performed
Document specific discharge instructions:
- Medications and potential serious side effects and drug interactions
- Adjunctive measures as indicated (splinting, rest, ice, elevation)
- Follow-up plan for any pending test results
- Recommended follow-up visits
- Need to bring all medications to follow-up visits
- Potential reasons to return to the ED for reassessment

PSORIATIC ARTHRITIS

EPIDEMIOLOGY

Psoriatic arthritis (PsA) is another autoimmune seronegative spondyloarthropathy with joint, periarticular, skin, and eye involvement and is second in prevalence to RA as a progressive inflammatory arthritis. PsA occurs in 10% to 40% of patients with psoriasis; it does not have a significant gender predominance but often occurs in familial clusters. Onset typically takes place in the fourth or fifth decades of life, long after the skin disease has begun, but there is a juvenile-onset variant that usually appears before psoriasis lesions do (frequently with a positive family history).

PATHOPHYSIOLOGY

The trigger and exact pathogenesis of PsA remain unknown, but inflammation and autoimmunity both play a role, with complex interactions between infection, trauma, host genetics, and abnormal responses from several cell lines. Its histopathology resembles that of RA, but PsA is associated with less synovial hyperplasia, fewer macrophages, and greater angiogenesis, along with higher levels of cytokines. Activated CD4+ T cells are found throughout the skin lesions and synovium; CD8+ T cells also play a major role.

Onset is usually insidious, though sometimes abrupt. Trauma to a joint may precipitate a flare at that site. Several patterns of joint involvement occur, most commonly an asymmetric oligoarthritis similar to reactive arthritis or a symmetric polyarthritis similar to RA. Spondylitis may be prominent. Most patients with PsA do very well, with severe and progressive disease developing in less than 25%. A rare subtype includes pustular acne and osteomyelitis. HIV-infected patients manifest a more severe and destructive form of PsA.

PRESENTING SIGNS AND SYMPTOMS

A combination of arthritis, enthesitis, tenosynovitis, and dactylitis should be sought in patients with psoriasis or a family history of it. Common forms of PsA affect the fingers (scattered DIP, PIP, and MCP joint involvement), feet (MTP joints), and less commonly the larger peripheral joints, sternoclavicular joint, or TMJ. Spinal pain, stiffness, and sacroiliitis are common, especially in men, but often begin later in the course. Systemic symptoms are uncommon.

The scalp, umbilicus, or gluteal folds should be examined for psoriasis if skin lesions are not obvious. Nail lesions (onycholysis, ridging, pitting) are common clues. Conjunctivitis and iritis may occur. Rarely, aortic regurgitation, conduction blocks, and atlantoaxial subluxation have been reported.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Although PsA may have several patterns of joint involvement, its skin lesions and nail changes assist in diagnosis. Psoriasis must be distinguished from eczema and seborrheic dermatitis. The keratoderma blenorrhagica of reactive arthritis may be difficult to distinguish from pustular psoriasis, and both diseases include conjunctivitis. The finger involvement of OA often includes Heberden and Bouchard nodes, whereas PsA does not. Vasculitis, rheumatoid nodules, and joint crystals are not a part of PsA.

Laboratory studies are generally unnecessary unless the patient is febrile and should have normal results in those with PsA. RF is negative. Joint fluid is inflammatory, with a predominance of polymorphonuclear neutrophils. Radiographs show differences from RA. In PsA, proliferative bone formation is often seen around marginal erosions, joint fusion and periostitis may be present, and bone density is usually preserved. Patients with PsA may have erosion of the terminal phalangeal tufts (acroosteolysis), bony ankylosis, or “pencil-in-cup” deformities in the digits (whittling of the distal end and cupping of the proximal end of phalanges). The spine often shows asymmetric sacroiliitis, large asymmetric syndesmophytes, and asymmetric paravertebral ossification.

TREATMENT AND FOLLOW-UP

Similar to other arthritides, most patients are managed as outpatients with NSAIDs, general measures, and primary care follow-up, unless infected. Occasionally, one NSAID may aggravate the skin lesions; if so, a different NSAID family should be tried. Flare-up in a single joint may be treated intraarticularly with a corticosteroid. Severe progressive disease warrants rheumatologic and possibly orthopedic referral. Dermatologic referral helps with skin lesions, which are treated separately with topical agents, retinoic acid derivatives, or psoralen with ultraviolet light. Poor responders (skin, joint, or both) may benefit from methotrexate or etanercept, and recent studies with anti-TNF agents show great promise. Other DMARDs and immune modulators may be useful. All immunosuppressive agents are risky in HIV-infected patients.

JUVENILE IDIOPATHIC (RHEUMATOID) ARTHRITIS

EPIDEMIOLOGY

Juvenile rheumatoid arthritis (JRA), the most common childhood connective tissue disease, occurs in patients up to 16 years of age. JRA is actually a collection of distinct inflammatory illnesses linked by synovitis, patient age, and limited knowledge of pathogenesis. Juvenile idiopathic arthritis (JIA) is the new name that has evolved for this group and includes more subtypes than found in the traditional JRA classification. Although most children do well in the long term, these arthritides frequently do result in chronic pain and significant functional and emotional disability. Prevalence in the United States is generally estimated to be 1 to 2 per 1000 children. The typical age at onset varies with the subtype, but more than half develop by the age of 5. Systemic JIA has no gender preference, but females predominate in other subtypes. In the
United States, whites and blacks appear to be at equal risk, but its incidence in Native Americans is higher.

PATHOPHYSIOLOGY

Causes remain unclear, but the pathogenesis includes an abnormal immune response to infection, stress, or environmental factors that is influenced by genetic background. Viral triggers have been postulated but not identified. Immune-pathogenesis is complex. T cells respond to antigens in the synovium, especially in the setting of specific HLA types. Cellular infiltration initiates a cascade of events consisting of release of various cytokines, B-cell activation, and complement fixation. Synovitis with villous hypertrophy, vascular hyperplasia, and edema results, sometimes with pannus formation and its erosion of bone and cartilage.

PRESENTING SIGNS AND SYMPTOMS

JRA and JIA may be especially difficult to identify in preverbal age children, in whom changes in motor activities (crawling, walking, running, holding a cup or spoon) are important clues. Joint complaints in children should be taken seriously, with a close look for objective findings. Pain is usually mild and may be quantifiable with pediatric pain scales. Ask about systemic symptoms (fever, weakness, fatigue), other organ symptoms (GI, eyes, skin), growth and development, and recent injuries, illnesses, or exposures. Consider trauma (and abuse), attendant bruising, and progressive swelling during the visit. Carefully check all joints, not just the most symptomatic. Examine the child for evidence of infection or other involvement, such as rashes, uveitis, carditis, or organomegaly. Major subtypes of JIA include systemic arthritis, oligoarthritis, polyarthritis, enthesis-related arthritis, and PsA.

Systemic arthritis (10% to 15% of cases of JIA) is the most dramatic finding, with systemic symptoms and onset usually occurring before the age of 4. Diagnostic criteria include high spiking fevers (>39°C) with daily return to normal (or below) for at least 2 weeks, arthritis that may follow the fever, and systemic involvement as shown by one or more of the following:

- Rash—evanescent, salmon-colored macules, often seen with a daily fever spike
- Generalized lymphadenopathy
- Serositis—pericarditis in more than one third, but tamponade is rare
- Hepatomegaly or splenomegaly

Systemic symptoms usually resolve within 1 year, but half will evolve into chronic polyarthritis and 25% will be result in erosive joint disease. The 15-year survival rate has been reported to be only 86%.

Oligoarthritis (35%) involves fewer than five joints in the first 6 months of disease, often large joints such as the knee or ankle but not the hip. Affected children are mostly girls (3:1) aged 1 to 4. Uveitis develops in about 15%. Although only about 25% of cases remit within 5 years, bone or cartilage destruction does not develop in most children.

Polyarthritis (30% to 40%) involves five or more joints, large and small, and resembles adult RA. Systemic symptoms are mild and fever is low grade. Rheumatoid nodules may be found. Micronodulat and cervical spine involvement occur, and there is a risk for atlantoaxial subluxation. At least two thirds are RF positive, which portends a greater risk for the development of severe erosive disease.

Additional subtypes include enthesitis-related arthritis (4:1 male preponderance, usually age >8, often HLA-B27 positive, spinal involvement) and PsA (pauciarticular, skin psoriasis or family history, nail changes, dactylitis), which often precedes any skin lesions by years. Other children demonstrate overlap patterns.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Unfortunately, the diagnosis of JIA can be difficult and requires a course of the disease over time, and the differential is long, so a single ED visit is highly unlikely to result in a specific diagnosis. Diagnosis of JIA requires true arthritis (swelling or at least two of the following: heat, limited ROM, tenderness, pain on motion), at least a 6-week duration, age younger than 16, and absence of another known cause. The fever pattern and rash of systemic JRA are distinctive but not conclusive.

Of course, the major concern is identifying active bacterial infection. Infectious arthritides such as Lyme disease (exposure, recent classic rash, neurologic involvement), parvovirus, Kawasaki disease (mucosal involvement), or tuberculosis should be considered. Rheumatic fever is often accompanied by exquisite joint tenderness, high spiking fevers, and migratory polyarthralgia, along with chorea or carditis.

Other rheumatologic possibilities include systemic lupus erythematosus, juvenile dermatomyositis, autoimmune hepatitis, sarcoidosis, and drug reactions. Joint pain occurs with hemoglobinopathies, hemophilies, and leukemias. Localized pain may be traumatic. Diffuse musculoskeletal pain and systemic symptoms (not fever) occur with childhood fibromyalgia.

No diagnostic studies prove the presence of JIA. CBC, urinalysis, and ESR or CRP are appropriate in the ED. In systemic JIA, severe nonhemolytic anemia, WBC count lower than 20,000/mm³, thrombocytosis, and an ESR higher than 100 mm/hr are common. In other forms, abnormalities are modest. Normal or low platelet counts suggest another diagnosis or a serious complication—rarely, macrophage activation syndrome with disseminated intravascular coagulation, severe anemia, leukopenia, and liver dysfunction develop in children with systemic JIA. Typical synovial fluid WBC counts are approximately 10,000 with JRA, but a range from 600 to 100,000 is reported. Gram stain and culture are obviously critical in evaluating infection. A febrile child requires more extensive evaluation to search for the source of the fever, particularly with a fever of unknown origin.

Radiographic studies help eliminate trauma, tumors, avascular necrosis, and infection. Abnormalities with JRA may include osteoporosis, periostitis, loss of joint space, erosions, and nonspecific soft tissue swelling. Late-stage disease shows joint destruction and fusion.
Initial treatment decisions in the ED usually focus on concern for differential diagnoses (trauma, infection) and the need for analgesia. If a fracture is suspected, a splint, ice, and elevation are used until trauma is ruled out. Decisions regarding antibiotic administration must be based on a thorough clinical evaluation plus the results of synovial fluid analysis.

NSAIDs are first-line medications for pain in all forms of JIA. Try ibuprofen (30 to 40 mg/kg/day divided into three doses) or naproxen (10 to 20 mg/kg/day divided into two doses). Recognize that adverse effects are somewhat different from those in adults. When the need for long-term use becomes apparent, long-acting preparations (napometone, etoladac once a day) are available. Acetaminophen or tramadol are also effective for pain, and temporary joint immobilization or support and ice packs help. Oral opioids may be needed for severe acute situations (oxycodone, 0.05 to 2.0 mg/kg/day divided into 4-hour dosing) or severe chronic disease (methadone often used).

About half of JIA patients experience adequate improvement with NSAIDs and the multidisciplinary measures that are essential for pediatric patients with prolonged painful illnesses. Education, physical therapy, and occupational therapy are critical, especially daily ROM exercises. General health maintenance, child and family counseling, cognitive behavioral therapy to manage pain, physical conditioning, and sleep hygiene are all part of a team approach to long-term management. Children who fail to improve will require DMARDs, but these drugs are not appropriate for ED initiation. Methotrexate has been the most frequently used agent, but etanercept and infliximab are highly promising new options. Adjunctive medications include sulfasalazine and low-dose prednisone.

Disposition decisions may be more difficult than in adults, especially with febrile children. Patients should be admitted for severe pain that persists despite ED treatment, as well as for diagnostic confusion, toxic appearance, suspicion of joint or systemic infection, or fever (unless it has an obvious, easily distinguishable cause). Septic arthritis or osteomyelitis must always be considered, especially with systemic symptoms or another site of infection. Transient synovitis of the hip is the most common cause of hip pain, associated with systemic symptoms or another site of infection. Severe pain, acute onset, ESR higher than 20 mm/hr, or temperature above 37.5°C suggests a septic hip. Transient synovitis of the hip is usually characterized by a “painless limp” caused by limited abduction and limited internal rotation. The child’s gait should be examined and gait observed, although the findings are nonspecific. The usual long-term result is a variable amount of restricted motion, along with slight shortening of the limb and an insignificant limp.

**DIFFERENTIAL DIAGNOSIS**

Several other entities may cause hip problems and limping, and distinction may not be possible in a single ED visit. Constitutional symptoms, fever, and associated disorders are not part of LCP disease. Radiographs are often tremendously helpful in making the diagnosis, as is nuclear scintigraphy. Septic arthritis or osteomyelitis must always be considered, especially with systemic symptoms or another site of infection. Severe pain, acute onset, ESR higher than 20 mm/hr, or temperature above 37.5°C suggests a septic hip. Transient synovitis of the hip is the most common cause of hip pain, with age at peak onset similar to that for LCP disease, but it usually resolves within a month; about half are initially seen in an acute stage, unlike LCP disease. Persistent synovitis may follow a course consistent with LCP disease. Other inflammatory diseases (JIA, rheumatic fever) usually have other joint involvement or systemic findings (or both). Slipped capital femoral epiphysis (SCFE) tends to occur at older ages (12 to 16 in boys, 10 to 14 in girls). Those with stable SCFE have an intermittent limp and pain with a chronic onset, whereas unstable SCFE is often manifested acutely after a twisting injury. The diagnosis of SCFE is usually made with plain films, although CT or MRI is sometimes needed.

**LEGG-CALVÉ-PERTHES DISEASE**

Legg-Calvé-Perthes (LCP) disease is an idiopathic pediatric form of avascular necrosis of the femoral head that may result in some flattening of the femoral head (coxa plana). It is a self-limited disease, but permanent deformity and restricted motion may result. LCP disease affects boys much more often than girls (4:1 to 5:1) and usually becomes evident between the ages of 5 and 7 (range, 2 years to teens). It is more common in shorter children with delayed bone age. A family history is positive in about 10%. The incidence of LCP disease also varies with ethnicity, being higher in Asians and central Europeans. Its relationship to trauma is unclear.
radiographs allow diagnosis and staging of LCP disease, with some help in prognosis.

**TREATMENT AND DISPOSITION**

Mild analgesics may be used as needed. Further treatment of LCP disease is done in the outpatient setting, with orthopedic consultation. “Containment” refers to reducing the pressure force on the hip by varus repositioning, with the goals of keeping the femoral head contained in the acetabulum, assisting blood flow, and molding its shape on remodeling. This is usually achieved by braces, but operative intervention may be required. Occasionally, temporary periods of rest are needed.

Systemic Lupus Erythematosus

James G. Adams

EPIDEMIOLOGY

SLE is more common by a ratio of 12:1 in women aged 15 to 45 years and by a ratio of 2:1 in younger and older women. The overall prevalence of this disease is about 1 in 1000. In most studies of SLE, about 90% of enrollees are women. In the United States, the disease is three times more common in black women than in white women. In addition to genetic factors, age, sex, race, and socioeconomic status have an impact on disease expression and prognosis. With optimal management, the 20-year survival rate approaches 70% and the 1-year survival rate is about 90%.

PATHOPHYSIOLOGY

SLE is a prototypic autoimmune disease characterized by tissue damage from excessive antibody production and immune complex deposition. The chronic inflammation characteristic of the disease originates from overproduction of autoantibodies and failure of the body to suppress them. Nearly every tissue in the body can be affected. Autoantibodies directly react to human antigens, immune complexes are deposited in tissue and blood vessels, and the complement cascade is activated, which results in inflammation and organ damage.

In some patients the illness is mild. Other patients suffer early, catastrophic organ damage. Early deaths are frequently due to injury to the kidney and brain. Later deaths often occur as a result of acute myocardial infarction, stroke, or infection. Steroids used for treatment may cause or worsen complications.

Acknowledgment and thanks to Clare Sercombe for contributions to the first and second editions of this chapter.

PRESENTING SIGNS AND SYMPTOMS

The triad of fever, joint pain, and rash in a woman of child-bearing age suggests SLE. The most well-recognized cutaneous finding is the red, raised butterfly rash (Fig. 108.1), but malaise, fatigue, aches, fever, and weight loss are the most common symptoms. The rash, which does not cross the
Clinical manifestations range widely from mild to life-threatening. About half of patients have severe disease, defined as complications that threaten life or organ function.

Some rash or arthritis (or both) develops in a substantial majority of patients. At least half of patients have the Reynaud phenomenon, mucous membrane involvement, and renal or central nervous system involvement. About half of patients report photosensitivity. Pleurisy, vasculitis, or gastrointestinal involvement will develop in a quarter to a third of patients. Less common but important manifestations include pancreatitis, myositis, and myocarditis.

Differential Diagnosis and Medical Decision Making

Arthritis, Arthralgia, Myalgia, and Osteonecrosis

Almost all patients occasionally have arthralgias and myalgias. The hand inflammation is symmetric, as in rheumatoid arthritis, but joint deformities are less common. “Hitchhiker’s thumb” (hyperextension of the interphalangeal joint of the thumb) develops in 30% of patients. Tenosynovitis and tendon rupture may also occur, especially in patients taking corticosteroids. In addition, vascular necrosis of the large joints, especially the femoral heads, may be present as a result of ischemia caused by the vasculitis or as a complication of corticosteroid therapy.

Skin

The characteristic facial eruption, seen in up to 40% of patients, may be the first sign or may accompany flares of the disease. It can be exacerbated by exposure to ultraviolet light.

Kidneys

Clinical nephritis, defined as persistent proteinuria, develops in approximately 50% of patients with SLE, although mesangial and glomerular immunoglobulin deposition occurs in almost all patients. Usually, the nephritis does not cause any symptoms until it progresses to an advanced stage. Serum creatinine is an important but insensitive indicator of early renal disease because many nephrons must be damaged before the creatinine level is elevated. Renal complications are recognized by hematuria, proteinuria, and red blood cell casts. Active urine sediment with excretion of red blood cell casts and increasing proteinuria is cause for concern.

Patients with active urine sediment may benefit from aggressive steroid or other immunosuppressive therapy. Indications for treatment include worsening renal failure, decreasing serum complement levels, increasing anti-double-stranded DNA levels, and nephritic urinary sediment, especially when accompanied by increasing or nephrotic-range proteinuria.7

Central Nervous System

Seizures, stroke, migraines, peripheral neuropathies, and psychosis are common. These symptoms may appear early but are rarely the initial sign of SLE. Central nervous system involvement develops in approximately 50% of patients with SLE. Full recovery from the neuropsychiatric manifestations occurs in approximately 70% to 85% of patients, although mortality from such events is 10% to 15%.

Seizures are the most frequent central nervous system manifestation. Strokes as a result of vascular inflammation and thrombosis are also common, especially in association with antiphospholipid syndrome.

Cerebritis should be considered when a patient with SLE exhibits a change in behavior or altered mental status. Infection should also be considered, particularly in patients receiving immunosuppressive therapy. These patients are at risk for bacterial, fungal, and tuberculous infections, in addition to brain abscesses. A head computed tomography scan and lumbar puncture are generally required to clarify the diagnosis. Symptoms may range from subtle changes in behavior to frank psychosis. Steroids are an important therapy for patients who have lupus-associated cerebritis.

Cardiovascular System

Pericarditis

Pericarditis is the most common heart-related problem and is reported to occur in 20% to 30% of patients, but it is present in up to 60% at autopsy. Electrocardiographic (ECG) findings

See Box 108.1, Criteria for the Classification of Systemic Lupus Erythematosus, online at www.expertconsult.com
BOX 108.1 Criteria for the Classification of Systemic Lupus Erythematosus*

Malar Rash
Fixed erythema, flat or raised, over the malar eminences with sparing of the nasolabial folds

Discoid Rash
Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions

Photosensitivity
Rash as a result of an unusual reaction to sunlight, as determined by the patient’s history or physician observation

Oral Ulcers
Oral or nasopharyngeal ulceration, usually painless, observed by the physician

Nonerosive Arthritis
Involving two or more peripheral joints and characterized by tenderness, swelling, or effusion

Pleuritis or Pericarditis
Pleuritis
  • Convincing history of pleuritic pain or a rub heard by the physician or evidence of pleural effusion

Pericarditis
  • Documented by electrocardiogram or rub or evidence of pericardial effusion

Renal Disorder
Persistent proteinuria greater than 0.5 g/day or greater than 3+ if a quantitative assay is not performed
Cellular casts—may be red blood cell, hemoglobin, granular, tubular, or mixed

Seizures or Psychosis
Seizures
  • In the absence of offending drugs or known metabolic derangement (e.g., uremia, ketoacidosis, electrolyte imbalance)

Psychosis
  • In the absence of offending drugs or known metabolic derangement (e.g., uremia, ketoacidosis, electrolyte imbalance)

Hemolytic Disorder
Hemolytic anemia with reticulocytosis
Leukopenia—less than 4000/mm³ on two occasions
Lymphopenia—less than 1500/mm³ on two occasions
Thrombocytopenia—less than 10,000/mm³ in the absence of offending drugs

Immunologic Disorder
Anti-DNA—antibody to native DNA in abnormal titers
Anti-Sm—presence of antibody to Sm nuclear antigen
Positive finding of antiphospholipid antibodies based on the following:
  • Abnormal serum concentration of IgG or IgM anticardiolipin antibodies
  • Positive test for lupus anticoagulant using a standard method
  • False-positive test result for at least 6 months and confirmed by Treponema pallidum immobilization or a fluorescent treponemal antibody absorption test

Positive ANA Test
Abnormal ANA titers by immunofluorescence or an equivalent assay at any time in the absence of drugs

ANA, Antinuclear antibody; anti-Sm, anti-Smith; IgG, immunoglobulin G; IgM, immunoglobulin M.
*Based on the American Rheumatism Association revised criteria for the classification of lupus. The criteria consist of conditions associated with systemic lupus erythematosus, including clinical symptoms, systemic complications, and diagnostic and laboratory test findings (see text for discussion).
alone may lead to the diagnosis because the pericarditis can be clinically inapparent. Alternatively, some patients will have fever, tachycardia, chest pain, and a cardiac rub. The pericarditis is usually fairly benign and responds well to ibuprofen or, in severe cases, to corticosteroids. Pericardial effusion, typically a transudative serous fluid, occurs in about 20% of patients. Tamponade is rare but has been noted. An uncommon but dangerous complication is purulent pericarditis, which should be suspected in patients who appear especially ill. Typical causes are *Staphylococcus aureus* and *Mycobacterium tuberculosis*. Purulent pericarditis is exudative with a high C-reactive protein level and elevated white blood cell count.

**Myocarditis**
Myocarditis is rarely diagnosed clinically but is found on autopsy in about 40% of patients. The 10% of patients in whom the diagnosis is made typically have symptoms that resemble those of cardiomyopathy, including congestive heart failure, ventricular dysrhythmia, tachycardia, and nonspecific ECG changes. Severe myocarditis should be treated with high-dose systemic corticosteroids, control of hypertension, and correction of volume overload.

**Endocarditis**
Libman-Sachs vegetations, present in up to 10% of patients with SLE, are growths on heart valves that usually cause no symptoms. Occasionally, these vegetations may be complicated by infection, valvular dysfunction, and rarely thromboembolism. The mitral valve is most commonly involved, although all four valves may have vegetations.

**Coronary Artery Disease and Coronary Vasculitis**
Accelerated atherosclerosis as a result of corticosteroid use may cause coronary ischemia. Mortality from coronary artery disease is seen in up to 30% of patients with SLE despite improved survival of patients with renal and cerebral SLE. Hypertension, smoking, and hypercholesterolemia significantly increase the risk for mortality in these patients. Patients with acute cardiac ischemia should be treated with standard interventions.

Coronary vasculitis is rare and best treated with steroids. Differences in treatment make the distinction between coronary vasculitis and coronary artery disease important. The diagnosis can be made by coronary angiography. Evidence of aneurysmal dilation of the coronary arteries is seen in patients with coronary vasculitis.

**Hypertension**
Between 25% and 50% of patients with SLE often have systemic hypertension as a result of lupus nephritis and steroid use.

**PULMONARY SYSTEM**

**Pleuritis**
Pleurisy and pleural effusions occur in more than half of patients with SLE. The pleural effusions are usually small and bilateral but can occasionally be very large. Pleural fluid is generally exudative, with glucose levels similar to serum glucose levels. In contrast, the pleural fluid of patients with rheumatoid arthritis has very low glucose levels.

**Pneumonitis**
Pneumonitis in patients with SLE causes diffuse interstitial infiltrates, although patients have usually had the disease for several years before they suffer from pneumonitis. Bacterial, fungal, and opportunistic infections must be considered before confirming the diagnosis, especially in patients taking immunosuppressive agents. Patients with SLE are particularly at risk for pneumococcal disease, in part because of autosplenectomy or splenic dysfunction.

**Pulmonary Fibrosis**
Chronic interstitial infiltrates leading to pulmonary fibrosis may also develop in patients with SLE. These patients need inpatient treatment, and their condition may progress to chronic hypoxia, pulmonary hypertension, and right-sided heart failure.

**Shrinking Lung Syndrome**
When a patient has shortness of breath, low lung volumes seen on a chest radiograph, and no other identifiable cause, shrinking lung syndrome is signaled. An elevated diaphragm but clear lung fields is characteristic. This syndrome may be chronic as a result of impaired respiratory mechanics, weak muscles, and poor diaphragmatic function. If the findings are acute, the patient may have a good response to steroids.

**GASTROINTESTINAL SYSTEM**
Mucous membrane lesions (small, shallow ulcerations in the mouth) occur in up to 19% of patients. Oral ulcerations usually accompany disease flares. Esophageal dysmotility is occasionally seen; however, it is much less common in patients with SLE than in patients with scleroderma.

Patients with intestinal pseudoobstruction may have crampy abdominal pain and a clinical and radiographic picture consistent with obstruction. They should be observed for resolution.

Mesenteric vasculitis is the most serious gastrointestinal complication. Patients have abdominal pain and, typically, bloody diarrhea along with evidence of vasculitis elsewhere. Bowel vasculitis may progress to perforation, gangrene, and peritonitis.

**HEMATOLOGIC DISORDERS**
Anemia, which affects up to 40% of patients with SLE, may result from hemolysis, drugs, renal disease, blood loss, or chronic disease. The most important cause is autoimmune hemolytic anemia. The Coombs test, which detects hemolysis resulting from hemolysis, drugs, renal disease, blood loss, or chronic disease, is usually positive.

Thrombocytopenia occurs in 25% of patients. Antiplatelet antibodies may be the cause of the low platelet count seen in patients with active SLE. Treatment of severe lupus-related thrombocytopenia is controversial; some authors advocate the use of vinca alkaloids and intravenous gamma globulin.

An important cause of thrombocytopenia is thrombotic thrombocytopenic purpura, which may be difficult to distinguish from acute autoimmune hemolysis. Patients with thrombotic thrombocytopenic purpura typically have low platelets, hemolytic anemia, central nervous system dysfunction, renal insufficiency, and fever. Symptoms can appear similar to those of a lupus flare. Treatment requires plasma exchange, so it is
important to either clinically distinguish or empirically initiate plasma exchange. Thrombotic thrombocytopenic purpura should be considered when a patient has a combination of microangiopathy, seizures, coma or altered mental status, and renal failure.

**DRUG-INDUCED LUPUS ERYTHEMATOSUS**

Procainamide has been known for more than 40 years to induce a lupus reaction. Since then, a large number of agents have been implicated, with hydralazine and procainamide being the most common (Table 108.1). The clinical manifestations vary, with most patients experiencing arthralgias and occasional pleuroperticardial pain. The full manifestations are present in less than 1% of patients taking high-risk drugs, although a positive antinuclear antibody titer can be found in more than 50%. Patients are generally women, middle-aged or older, and rarely African American, but this may be representative of the group of patients. The condition is usually reversible when drug therapy is stopped, with resolution occurring within days or weeks. Manifestations lasting for years have been reported. In patients with significant pleuroperticardial disease, a short course of tapered steroids has been used successfully once use of the implicated medication has been discontinued.

**TREATMENT**

Medical therapy attempts to reduce inflammation, suppress the immune system, and control pain. Nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, and immunosuppressive agents are the mainstays of treatment. Aspirin and other NSAIDs are the primary treatment of arthralgias, pleurisy, and pericarditis. The maximum standard recommended doses of these agents are usually needed. These agents should be avoided in patients with severe gastrointestinal complications, renal insufficiency, nephritis, or thrombocytopenia. Treatment with NSAIDs can worsen lupus nephritis, either by causing interstitial nephritis or by inhibiting prostaglandins.

Topical corticosteroids control most rashes. Although antiinflammatory and antimalarial drugs are often advocated for patients with minor symptoms to avoid the long-term complications of corticosteroid therapy, symptoms such as arthralgias, fatigue, pleurisy, and others may require lower-dose steroids, such as prednisone (0.5 mg/kg or less).

High-dose steroids (e.g., 1 mg/kg/day of prednisone or 1 g of methylprednisolone intravenously [IV]) are used when major organs are involved and also for hemolytic anemia and severe thrombocytopenia. For example, in patients with lupus-related cerebritis or acute worsening of lupus nephritis, 1 g/day of methylprednisolone IV may be given for several days.

Corticosteroids are associated with well-known complications, including steroid-induced diabetes, osteoporosis, weight gain, pancreatitis, osteonecrosis, accelerated atherosclerosis, and immunosuppression. Patients receiving chronic steroid therapy should be evaluated promptly for any episode of fever or potential infection. When patients who are taking corticosteroids have an acute serious illness or other physiologic stress (e.g., surgery, childbirth), they should also be given hydrocortisone (100 mg IV every 8 hours). Patients with overwhelming sepsis or shock should be given stress-dose steroids (e.g., 100 mg of hydrocortisone IV), in addition to the usual treatment with broad-spectrum antibiotics and intravenous resuscitation fluid.

Antimalarial drugs are effective for the cutaneous and musculoskeletal manifestations of SLE. Hydroxychloroquine and chloroquine are given on an outpatient basis in a loading dose for 4 weeks, followed by maintenance dosing once the symptoms are under control. Withdrawal of the drug may result in flare of the disease.

Immunosuppressive agents (azathioprine, methotrexate, cyclophosphamide) are reserved for patients with severe renal or cerebral disease in whom other therapies have failed and for patients who cannot tolerate corticosteroids. Studies of the use of immunosuppressants have shown decreased chronic renal scarring and a reduced likelihood of end-stage renal disease without an increase in mortality. The toxic effects of such drugs are numerous and include myelosuppression, risk for neoplasms, and infections, especially with gram-negative organisms, encapsulated gram-positive organisms, herpes zoster, and opportunistic organisms. Febrile patients who are taking azathioprine, methotrexate, or cyclophosphamide should be admitted regardless of whether a source is evident because gram-negative or streptococcal sepsis occurs in this population. Immunosuppressed patients with localized herpes zoster should be admitted for intravenous acyclovir treatment to prevent viral dissemination.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with known disease and increasing arthritic pain or with a mild flare and no fever may be treated with NSAIDs

*Removed from the market because of lupuslike syndrome.
or corticosteroids as an outpatient. Pleuritis and arthralgias can be treated on an outpatient basis. It may be prudent to perform urinalysis to ensure that there is no evidence of renal involvement, which might signal significant disease activity. In the absence of major organ involvement, the patient can be scheduled for prompt follow-up with a rheumatologist.

Patients with a new diagnosis of pericarditis, myocarditis, pleural effusion, or infiltrates or with evidence of vasculitis or renal insufficiency should almost always be admitted to the hospital. If there is uncertainty regarding diagnosis or severity of any circumstance, patients should be admitted for observation, testing, and treatment. Patients with worsening disease who are taking large doses of steroids or immunosuppressive agents should be admitted for aggressive treatment.

Patients with evidence of lupus nephritis and worsening renal failure should be admitted for therapy with steroids and, frequently, immunosuppressive agents. The serum creatinine level may be elevated, but serious disease may be present even with normal creatinine levels. Proteinuria may be present, or red blood cell casts in urine may be the only sign of severe renal involvement. Patients with SLE have a higher risk for coronary artery disease, so a complaint of chest pain should prompt evaluation for cardiac ischemia. If pericarditis is suspected, evaluation for pericardial effusion may be necessary, although tamponade is rare. Patients with myocarditis should be observed for evidence of congestive heart failure and dysrhythmias.

Shortness of breath suggests lung infection from typical or atypical organisms. Opportunistic infection, tuberculosis, and lupus pneumonitis need to be considered. In a hypoxic patient, it is prudent to consider the possibility of pulmonary embolism secondary to antiphospholipid antibody with thrombosis. Patients with significant pleural effusions should be admitted for consideration of diagnostic thoracentesis and treatment. Pleural effusions may be complicated by infection, tuberculosis, or malignancy.

SLE predisposes patients to anemia and thrombocytopenia. Patients should be admitted if there is evidence of active hemolysis with decreased hematocrit levels or hemolysis that is evident on the blood smear. Patients with thrombocytopenia should be admitted if evidence of bleeding is seen or if platelet counts are severely decreased (<50,000/mm³). If the patient is actively bleeding, platelet transfusion is appropriate; however, rapid destruction of the platelets may occur. Simultaneous administration of intravenous corticosteroids and gamma globulin will aid in increasing the platelet count and decreasing the amount of platelet destruction.

Patients with evidence of arterial or venous thrombosis should be admitted for anticoagulation and possible embolec- tomy. Anticoagulation can be achieved acutely with heparin, although large doses are occasionally needed to overcome the antibody effect. The partial thromboplastin time (PTT), if not elevated, can be monitored to assess for evidence of adequate anticoagulation, with careful observation for bleeding in patients who are also thrombocytopenic. Otherwise, patients with a prolonged PTT and evidence of lupus anticoagulant can be monitored with thrombin times if necessary. Patients with an international normalized ratio of less than 2.5 should nevertheless be considered to have a possible thrombus if they have a history of antiphospholipid syndrome.

Pregnant patients should undergo early follow-up with a high-risk obstetrician. Emergency delivery for a pregnant patient with SLE should include stress-dose steroid administration and close observation of the neonate for congenital complete heart block (i.e., neonatal lupus). Emergency cardiac pacing may be necessary for the infant.

Connective Tissue and Inflammatory Disorders

Raveendra S. Morchi

PATHOPHYSIOLOGY

Activation of the innate immune system, possibly in response to environmental or as yet unrecognized infectious triggers, results in elevated levels of type 1 interferon and characteristic cytokine profiles, including increased B-cell–activating factor. The ensuing infiltration of the salivary or lacrimal glands by periductal and periacinar foci of aggressive T lymphocytes marks the adaptive immune response. What follows is destruction and eventual loss of exocrine function.\(^1\) In addition to T cells, polyclonal activation of B cells within and at the border of foci can result in hypergammaglobulinemia.

More recently, animal models suggest that lacrimal and salivary gland dysfunction need not always rely on innate and adaptive inflammation as a prerequisite. Rather, they may be related to abnormalities in water and ion channels as a result of genetic, hormonal, or autonomic imbalances antecedent to the inflammatory response.\(^7\) Other exocrine glands in the body (lining the respiratory tree, integument, and vagina) can also be affected in Sjögren syndrome and produce a dry cough, dry skin, dysuria, or dyspareunia.

Regardless of whether the lacrimal and salivary gland dysfunction is bound to an inflammatory infiltrate, it is known that the hallmark of Sjögren syndrome is eventual systemic lymphocyte activation, which means that organs other than glandular tissue can be affected. Such a level of immune activation could be responsible for the increased risk for lymphoproliferative disorders and autoimmune endocrinopathies that have been noted in patients with Sjögren syndrome.

PRESENTING SIGNS AND SYMPTOMS

GLANDULAR

Dry eyes, foreign body sensation, ocular grittiness, fatigue, and easy irritation are common complaints related to the lacrimal system. The patient may also have blurred vision, trouble with bright lights, or red eye. Signs include keratitis, conjunctivitis, mucous filaments at the inner canthus, blepharitis from meibomian gland dysfunction, and lacrimal enlargement.

Dry mouth and lips, an unpleasant taste in the mouth, difficulty chewing and swallowing dry food, and possibly a clicking quality of speech from the tongue sticking to the hard palate are all symptoms of diminished saliva production. Signs of poor salivary flow include secondary dental caries,

SJÖGREN SYNDROME

EPIDEMIOLOGY

Sjögren syndrome is a slowly progressive dysfunction of the lacrimal and salivary glands. The resulting exocrinopathy produces the characteristic symptoms of dry eyes and dry mouth. An incidence of 4 per 100,000 per year has been noted. Ninety percent of cases occur in women, and the incidence increases with age. Patients may be anywhere in age from the fourth to the eighth decades.

KEY POINTS

- Dry eyes and dry mouth unrelated to a medication side effect suggest primary Sjögren syndrome.
- Loss of sensation, paresthesias, and pain in the digits on exposure to cold or emotional stress are characteristics of Raynaud phenomenon.
- Many patients in whom systemic sclerosis eventually develops are initially found to have symptoms of Raynaud phenomenon and symmetric, nonpitting digital edema (without any fibrosis).
- Gastrointestinal symptoms in the presence of symmetric, digital edema or fibrosis suggest systemic sclerosis.
- Symptoms of edema and fibrosis proximal to the elbows or knees can represent an aggressive, diffuse form of systemic sclerosis with a high likelihood of internal organ involvement.
- An angiotensin-converting enzyme inhibitor should be considered for hypertensive patients with a presumed or definite diagnosis of systemic sclerosis.
- The diagnosis of sarcoidosis should be suspected in patients with only bilateral hilar lymphadenopathy on chest radiography, especially if they either have long-standing pulmonary complaints or are entirely asymptomatic.
- Early, vague subjective symptoms of fatigue, joint pain, or muscle discomfort may herald autoimmune disease.
GINGIVITIS, IRRITATION OF ORAL MUCOSA, ORAL CANDIDIASIS, PAROTID GLAND ENLARGEMENT, AND DIMINISHED POOLING OF SUBLINGUAL SALIVA ON DIRECT INSPECTION.

EXTRAGLANDULAR

The T- and B-lymphocyte activity that infiltrates exocrine glands can also affect other nonglandular organs. These extraglandular manifestations portend a worse prognosis. Fatigue, myalgias, arthralgias, arthritis, and subjective fever are nonspecific and will not help distinguish Sjögren syndrome. Most renal disease will be tubular in origin and related to invading lymphocytes. Signs can be minimal, but urinary sediment consisting of small amounts of protein or evidence of tubular malabsorption, with or without systemic acidosis (renal tubular acidosis), may be seen.

Patients may have abdominal pain or nausea and vomiting consistent with gastritis or hepatitis. In some instances there is an association between Sjögren syndrome and hepatitis C or celiac disease, another condition characterized by aggressive lymphocyte activity.

Patients may have symptoms of Raynaud phenomenon because of abnormal regulation of vascular caliber. Purpuric, maculopapular, or urticarial rash results from hypergamma-globulinemia or cryoglobulinemia secondary to polyclonal B-cell activation.

Peripheral (median or peroneal) and cranial (V, VII, VIII) neuropathies are secondary to autoimmune-mediated vasculitis. Central nervous system involvement is less common and consists of focal lesions mimicking multiple sclerosis, diffuse encephalopathy, or aseptic meningitis.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

If dry eyes and dry mouth dominate the clinical picture, the patient may have primary Sjögren syndrome. However, these symptoms can be associated with a number of other autoimmune disorders that more accurately characterize the clinical findings (rheumatoid arthritis, systemic lupus erythematosus, scleroderma), in which case such patients probably have secondary Sjögren syndrome (Box 109.1).

The cracker test, in which the patient tries to chew and swallow a dry cracker, is probably the most useful bedside diagnostic maneuver. Patients with Sjögren syndrome will have a difficult time completing this task, with adherence of food to the buccal mucosa. Slit-lamp testing with fluorescein may show epithelial defects over the cornea consistent with keratitis secondary to dryness. Rose bengal staining (Fig. 109.1) is generally regarded as a more sensitive means of depicting these defects but is usually performed by an ophthalmologist. The Schirmer test involves placing standardized tear testing strips between the unanesthetized eyeball and the lateral margin of the lower lid and noting advancement of a tear film over a period of 5 minutes. Anything less than 5 mm is considered abnormal.

TREATMENT

Treatment of Sjögren syndrome has two objectives: improve the symptoms of exocrine gland dysfunction and attempt to control the underlying autoimmune lymphocyte activity. The former has had more success than the latter.

XEROPHTHALMIA

Artificial tears with or without preservatives may be used throughout the day, and lubricating ointments can be used at night. Oral pilocarpine, 5 mg four times per day, will stimulate muscarinic gland receptors, increase lacrimal flow, and provide subjective improvement.3,4 More severely affected patients with keratoconjunctivitis sicca who are taking cevimeline, 30 mg three times per day, have reported a reduction in the severity of symptoms.5,6 Topical ocular nonsteroidal and steroidal preparations or topical 0.05% cyclosporine can be prescribed by an ophthalmologist for a short term.5 Occlusion of the nasolacrimal duct temporarily with plugs or permanently by surgical intervention is last-line therapy.
XEROSTOMIA

Though available, artificial saliva tends to be short-lived and less well accepted by patients. Meticulous oral hygiene is necessary to prevent dental caries, gingivitis, or periodontitis secondary to dryness. Sugarless cough drops (lemon drops) stimulate flow. Lifestyle modifications such as the use of a humidifier or avoidance of dry environments and excessive air conditioning can help retain moisture. Mycostatin oral suspension, Mycostatin vaginal tablets (also dissolve orally), or clotrimazole troches should be considered for the treatment of oral candidiasis in patients with Sjögren syndrome. Oral pilocarpine, 5 mg four times per day, or cevimeline, 30 to 60 mg three times per day, can stimulate muscarinic receptors and improve salivary flow in those with more significant symptoms.6,7,9 One must beware of side effects related to systemic muscarinic activation, including bradycardia, bronchospasm, gastrointestinal symptoms, or impaired mydriasis and trouble with night vision.

OTHER TYPES OF XEROSIS

Humidified air and guaifenesin are useful for a dry respiratory tree. Avoidance of tight or restrictive clothing and the use of moisturizing creams, lotions, and bathing products can help with dry skin. Mild corticosteroid cream may be added for pruritus. Propionic acid gel is an effective vaginal lubricant.

AUTOIMMUNE LYMPHOCYTE ACTIVITY

Nonsteroidal antiinflammatory drugs (NSAIDs) can be prescribed from the emergency department (ED) for symptomatic control of minor rheumatic complaints. Hydroxychloroquine has no clear benefit in ameliorating these symptoms.2 The rheumatologist may prescribe prednisone, methylprednisolone, cyclophosphamide, methotrexate, or azathioprine to control lymphocyte activity. Newer therapies include monoclonsal antibodies (rituximab) that target B cells.5 Future investigations are directed at blocking type 1 interferon, B-cell–activating factor, and other cytokines that link the initial innate immune response to the subsequent adaptive response composed of activated lymphocytes.

PATIENT DISPOSITION AND NEXT STEPS IN CARE

Patients with suspected primary or secondary Sjögren syndrome should undergo outpatient primary care and rheumatology follow-up within 2 to 4 weeks. Outpatient ophthalmology or dental evaluation is also advisable. Patients should be told to return to the ED for significant ocular pain or visual disturbance, which may signify keratitis and can be complicated by globe perforation.

SYSTEMIC SCLEROSIS (SCLERODERMA)

EPIDEMIOLOGY

Systemic sclerosis is a generalized thickening and fibrosis of the skin and internal organs that affects 1 in 4000 adults in the United States.10 Its incidence ranges from 2 to 23 cases per million per year.11 Women are more likely to be affected than men, with the onset of disease peaking between 30 and 50 years of age.

PATHOPHYSIOLOGY

Patients can have localized patches of skin fibrosis, or the disorder may progress to diffuse skin involvement with fibrosis and dysfunction of internal organs. Although the precise trigger is not known, an underlying functional and physiologic vascular abnormality is believed to play a central role. In association with oxygen radical species, findings include endothelial cell dysfunction and apoptosis, an imbalance favoring endothelin over prostacyclin, vascular smooth muscle hyperplasia, and pericyte prolifération in the perivascular space. Concomitantly, an adjacent inflammatory response occurs and is composed of lymphocytes, macrophages, and fibroblasts that lay down increasing amounts of extracellular matrix, including collagen.12 Cytokines and growth factors such as transforming growth factor-β and platelet-derived growth factor are involved in the amplification of this response, which includes activation and differentiation of fibroblasts.10 The types of systemic sclerosis are listed in Box 109.2.

PRESENTING SIGNS AND SYMPTOMS

Raynaud phenomenon is the initial complaint in the majority of patients and precedes clinically detectable skin fibrosis, probably because vascular malfunction antedates the edema and collagen deposition in patients with systemic sclerosis. The skin blanching associated with Raynaud phenomenon may not be present, but paresthesias or sensory deficits followed by throbbing pain in the fingers, toes, and sometimes the cheeks, nose, or tongue on exposure to cold are more
consistent findings. It should be noted, however, that systemic sclerosis never develops in most patients with Raynaud phenomenon.

Musculoskeletal complaints consisting of arthralgias, myalgias, and generalized weakness are nearly universal in patients with systemic sclerosis and other connective tissue disorders. Sometimes patients will have palpable or audible tendon friction rubs. Musculoskeletal problems are often some of the first symptoms and may be refractory to standard therapy with NSAIDs.

Skin findings are the most useful in the ED. Edema is a hallmark of early scleroderma, as well as rheumatoid arthritis, systemic lupus erythematosus, and other connective tissue disorders. Painless swelling of the fingers and hands is common (Fig. 109.2). Erythema and pruritus are associated findings caused by an early inflammatory response and deposition of components of the extracellular matrix. Nonpitting edema need not be limited to the distal end of extremities but may spread proximally or to the face and neck over the course of weeks.

Fibrosis can ensue in weeks or months. Gradually, collagen is deposited and the edematous areas are replaced by firm, thick, taut skin that may become bound to underlying tissue. In the fingers, tight skin can produce joint flexion contractures plus breaks or ulcerations as it is stretched over bony prominences (knuckles) in the condition termed sclerodactyly (see Fig. 109.2). Digital ulcerations, pitting scars, and loss of the finger pad can result from poor distal perfusion through intervening fibrotic tissue. This may be followed by calcium deposition (calcinosis).

A masklike appearance of the face (Fig. 109.3) with loss of the natural skin creases and diminished hair growth is characteristic. “Salt and pepper” alterations in pigmentation may be present. Disorganized arrays of blood vessels (telangiectases) scattered over the extremities, face, and mucous membranes are sequelae of deranged angiogenesis after the initial vascular obliteration and fibrotic inflammatory response. Gastrointestinal symptoms are very common and related to intestinal wall edema and fibrosis, which can occur anywhere from the esophagus to the rectum. Reflux esophagitis, strictures, and even Barrett esophagus can occur. Throughout the rest of the bowel, complications include smooth muscle dysfunction with dysmotility and ileus, pulsion diverticula as a result of uncoordinated peristaltic activity, bacterial overgrowth, and malabsorption. Nausea, anorexia, bloating, constipation, and diarrhea are potential complaints.

Pulmonary symptoms generally include dyspnea on exertion and a nonproductive cough. Interstitial fibrosis is more common in the diffuse form of scleroderma, and scattered rales may be heard. As with other fibrotic conditions, systemic sclerosis produces a restrictive lung disease. Pulmonary hypertension from obliteration of pulmonary vasculature associated with changes in the intimal and medial vessel walls can occur in the absence of significant interstitial fibrosis and is seen in a subset of patients with the limited form of systemic sclerosis.

Renal vascular involvement parallels that of other organs. The main difference is that when flow through the arcuate and interlobular renal arterioles is diminished secondary to the microvasculopathy and spasm characteristic of systemic sclerosis, the distal glomerulus and juxtaglomerular apparatus will respond to this decrease in perfusion by producing renin and beginning a cycle of fluid retention and vascular constriction via angiotensin II and aldosterone. The result is hypertension with systemic vasoconstriction, which can cause further damage to blood vessels and even hemolysis of red cells as they pass through the injured vasculature. In this sense, patients with renal involvement can seen be anywhere along a spectrum between asymptomatic hypertension and a

**Fig. 109.3** Facial features in scleroderma. Note the vertical lines or furrowing around the mouth in this patient with diffuse scleroderma. (From Goldman L, Ausiello D, editors. Cecil textbook of medicine. 22nd ed. Philadelphia: Saunders; 2004.)

**Fig. 109.2** Changes in the hands associated with connective tissue diseases. A, Edematous phase. B, Atrophic phase with contractures and skin thickening (sclerodactyly). (From Goldman L, Ausiello D, editors. Cecil textbook of medicine. 22nd ed. Philadelphia: Saunders; 2004.)
hypertensive emergency or malignant hypertension with characteristic funduscopic changes.

Cardiac inflammation results in pericarditis with effusion. In the myocardium, patchy areas of fibrosis can physically impair cardiac conduction or provide scar tissue that serves as points of electrical reentry. Secondary conduction deficits and supraventricular or ventricular arrhythmias will follow. Myocardial involvement and arrhythmias are asymptomatic in most, but dyspnea on exertion, congestive heart failure, syncope, or sudden death can occur. Additionally, coronary artery vasospasm may be associated with the underlying vasculopathy of systemic sclerosis.

Other features include thyroid, salivary, and lacrimal gland dysfunction secondary to fibrosis. Fibrosis in soft tissue can result in an entrapment neuropathy of susceptible peripheral nerves, including the median, lateral femoral cutaneous, trigeminal, and facial nerves. Men may have erectile dysfunction from impaired blood flow secondary to vasculopathy and fibrosis.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis for systemic sclerosis includes several other connective tissue diseases (Box 109.3).

Skin examination is the most important diagnostic tool for the emergency physician (EP). Nail fold capillary examination may be useful for patients with Raynaud phenomenon who do not yet have skin changes indicative of sclerosis. Using an ophthalmoscope and immersion oil applied to the skin, dilated and tortuous capillaries mixed with areas of capillary loss can be seen as evidence of a burgeoning connective tissue disease in patients with secondary Raynaud phenomenon.

Serum electrolyte levels should be measured and urinalysis performed to evaluate renal function. Because the disease does not usually involve the glomerulus or nephron tubular cells directly, but rather the arterioles upstream, findings on urinalysis are frequently normal or limited to mild proteinuria with few cells or casts. Therefore, elevations in serum creatinine alone in a patient with other clinical evidence of systemic sclerosis would raise the possibility of scleroderma renal disease.

A complete blood count and smear should be obtained for patients with suspected microangiopathic hemolysis from malignant hypertension. An electrocardiogram and rhythm strip can be evaluated for suspected conduction deficits or arrhythmia secondary to myocardial fibrosis.

Nonemergency work-up includes specific autoantibody profiling, gastrointestinal contrast studies for dysmotility, pulmonary function testing, echocardiography to evaluate myocardial contractile function or pulmonary hypertension, and biopsy to reveal the characteristic fibrotic skin or gland changes.

**TREATMENT**

Because the mechanics and primary inciting events of systemic sclerosis are not yet well understood, therapy is generally aimed at improving symptoms and curbing end-organ dysfunction. Treatment of Raynaud phenomenon includes lifestyle changes, calcium channel blockers, alpha-blockers, antiplatelet agents, and sympathectomy.

Musculoskeletal symptoms may respond to ibuprofen or another NSAID in standard doses combined with physical and occupational therapy.

Skin therapy includes moisturizers, topical glucocorticoid or antihistamine cream for pruritus, and local wound care with topical antibiotics for ulceration. High- or low-dose D-penicillamine cannot be recommended as an effective treatment at this time.

Gastroesophageal reflux responds to standard changes in dietary habits and daily oral administration of omeprazole, 10 to 20 mg. Refractory cases may require surgical intervention, and reflux esophagitis–induced strictures may need periodic dilation.

Pulmonary hypertension is managed with endothelin receptor antagonists, phosphodiesterase inhibitors, and prostacyclin analogues. Control of interstitial fibrosis has proved more difficult. Aggressive treatment with methotrexate, cyclophosphamide, or other immunosuppressives should be left to a specialist because their benefit is unclear.

Asymptomatic hypertension in a patient with known or suspected systemic sclerosis is presumed to be hypertensive in origin secondary to renal arteriolar disease and should be treated as such with an angiotensin-converting enzyme inhibitor. Oral administration of captopril, 6.25 to 12.5 mg three times per day, is a recommended starting point. These patients require close outpatient monitoring of renal function. Patients with a hypertensive emergency or malignant hypertension may require intravenous enalaprilat or tighter control of systemic vascular resistance and heart rate via short-acting agents. Dialysis and renal transplantation remain last-line treatments for patients whose condition progresses to end-stage renal disease despite medical management.

Current emerging therapies include intravenous immune globulin, mycophenolate mofetil, B-cell antibodies (rituximab), and autologous or allogeneic hematopoietic stem cell transplantation to curb the role of immune cells in the pathogenesis of systemic sclerosis. Interferon therapy, downstream...
tyrosine kinase inhibition, and other novel antifibrotic approaches may be used to limit fibroblast proliferation and collagen production in the future.17

**SARCOIDOSIS**

**EPIDEMIOLOGY**

Because granulomatous inflammation can be due to many causes, the exact worldwide prevalence and incidence of sarcoidosis are not known. Most patients with the disease are younger than 50 years, and the peak age seems to be 20 to 39 years. Women are affected slightly more often than men. Worldwide, the majority of cases occur in white persons in northern European countries, but in the United States the disease is more frequent in African Americans.18

**PATHOPHYSIOLOGY**

Sarcoidosis is characterized by the presence of noncaseating granulomas in multiple organs. Granulomas are composed of macrophages and other antigen-presenting cells, as well as T lymphocytes helping organize the response. They represent the immunologic reaction to organisms or antigens that cannot be properly disposed of and instead are simply contained and walled off. Sometimes the contents of the granuloma undergo what is described pathologically as caseous necrosis (i.e., the granulomatous response to tuberculosis). At other times necrosis is absent, and the granulomas are termed noncaseating. In sarcoidosis, noncaseating granulomas can be found anywhere in the body but are primarily situated in the mediastinal and hilar lymphatic tissue, airways, and pulmonary parenchyma. Respiratory or not, nearly every clinical manifestation of sarcoidosis can be traced to the physical presence of granulomas within the organ.

Although the exact cause of sarcoidosis is unknown, some evidence indicates that an environmental, chemical, or infectious agent provides the antigenic stimulus to macrophages. Once processed and presented, these antigens trigger a CD4+ T-cell–mediated reaction that subsequently incites increasing numbers of macrophages and neighboring epithelial cells to partake in the formation of noncaseating granulomas and thereby produce the clinical signs and symptoms of sarcoidosis.

In addition to the environmental trigger, a genetic component mediating T-cell hypersensitivity may be required. In this way, clinical sarcoidosis may develop in only a genetically susceptible individual exposed to the unidentified antigen.

**PRESENTING SIGNS AND SYMPTOMS**

Pulmonary disease is the hallmark of sarcoidosis. Granulomas occur throughout the mediastinal and hilar lymph nodes, in the lining of bronchi, and within the pulmonary parenchyma. Dyspnea on exertion, nonproductive cough, and nonspecific retrosternal chest pain are common complaints. Depending on the location and extent of the granulomatous tissue, patients may have primarily wheezing and a prolonged expiratory phase from endobronchial lesions or rales from parenchymal involvement. Alternatively, many patients have no symptoms and clear lung findings despite radiographic evidence of disease.

Skin lesions are present in up to 25% of patients (Fig. 109.4). Most are chronic and due to direct granulomatous involvement of the dermis. Unfortunately, they may take the form of papules, plaques, nodules, keloids at the site of surgical scars, or even lupus pernio (a violaceous discoloration of the nose, cheeks, chin, and ears). Thus it is difficult for the EP to make the diagnosis of sarcoidosis based on the presence of skin lesions alone.

Erythema nodosum may be one exception. Unlike other lesions, it is acute in onset and does not consist of granulomas but instead cellular inflammation and edema involving the dermis and subcutaneous tissue; it produces the characteristic raised, red, tender, nodular lesions most often seen on the anterior tibial surface. Erythema nodosum can be used to confirm the diagnosis of sarcoidosis in patients found to have bilateral hilar lymphadenopathy on chest radiography.

This combination of findings describes a subset of sarcoidosis patients said to have Löfgren syndrome. Note that erythema nodosum without bilateral hilar adenopathy may be present in a number of other infectious or neoplastic conditions and should not be considered diagnostic of sarcoidosis.
Ocular sarcoidosis most frequently takes the form of anterior uveitis with symptoms of eye pain, irritation, and visual disturbances, including red eye and photophobia. Cell and flare or even hypopyon may be seen on slit-lamp examination. Posterior uveal tract can also be involved, with signs of chorioretinitis noted on funduscopy. Keratitis and globe perforation are sequelae of corneal involvement, and nodules representative of granulomatous tissue can be seen on the conjunctiva of affected patients.

Cardiac disease, though less common, can be life-threatening. Appropriately placed septal granulomas can block the normal conduction system, with complete heart block being the most common manifestation. They may also serve as foci for electrical reentry and thereby predispose to arrhythmias. Within papillary tissue, granulomas can result in muscle dysfunction and secondary atrioventricular valve incompetence. Extensive ventricular muscle involvement or valvular insufficiency can result in congestive heart failure.

Musculoskeletal manifestations consist of symmetric arthralgias or inflammatory arthritis of the ankles, knees, wrists, and elbows. Most patients do not have a chronic destructive arthritis, however. Although lytic or sclerotic bony lesions can be noted in the hands and feet, many patients will be asymptomatic. Granulomatous muscle involvement is also often subclinical.

Neurologic complications develop in up to 10% of patients and can involve any part of the central or peripheral nervous system. Aseptic (predominantly basal) meningitis, encephalopathy, seizures, hypothalamic and pituitary disturbances (with diabetes insipidus or secondary thyroid or adrenal dysfunction), cranial neuropathies (especially unilateral or bilateral cranial nerve VII palsies), and communicating or noncommunicating hydrocephalus from granulomatous impairment of ventricular drainage are all potential intracranial manifestations. Peripheral neuropathies and spinal cord dysfunction are secondary to extracranial granulomatous inflammation.

Glandular exocrine insufficiency from granulomatous involvement can produce swollen lacrimal, parotid, and salivary glands, with resultant symptoms of dry eyes and mouth. Other signs and symptoms related to systemic T-cell activation and granuloma formation include nonthoracic lymphadenopathy, splenomegaly, fever, and malaise. Increased granulomatous calcitriol production with long-standing hypercalcemia and hypercalciuria may result in renal calcium deposition.

### Differential Diagnosis and Medical Decision Making

Pulmonary symptoms and typical radiographic signs in a young or middle-aged patient with erythema nodosum, iritis, or nonspecific, symmetric musculoskeletal complaints can help the EP distinguish sarcoidosis from other infectious or autoimmune processes (Table 109.1). Even then, a definitive bedside diagnosis may be difficult to make, and the EP may need to consider tuberculosis, histoplasmosis, community-acquired pneumonia, and lymphoma before diagnosing sarcoidosis (Box 109.4). Some of these patients will have to be admitted or treated empirically for an infectious process before a diagnosis can be secured via a more extensive workup. Given the array of organ systems affected and the lack of pulmonary symptoms in many patients, sarcoidosis may go unrecognized in the ED.

A chest radiograph is the most useful tool for patients with cough, dyspnea, or chest pain. Patients in whom the diagnosis of sarcoidosis is being considered because of erythema nodosum, iritis, or cranial neuropathy should also undergo chest radiography, even in the absence of pulmonary signs or symptoms. The four stages of pulmonary sarcoidosis are described in Table 109.2. Patients normally do not progress from one stage to the next. A higher stage indicates a lower likelihood of spontaneous resolution.

BP, Blood pressure; ECG, electrocardiogram; GERD, gastroesophageal reflux disease; NSAIDs, nonsteroidal anti-inflammatory drugs.
An electrocardiogram should be obtained for any patient with syncope, dyspnea, or rhythm abnormalities. Cardiac granulomas can produce first- through third-degree atrioventricular block, fascicular block, or bundle branch block.

Patients should undergo a slit-lamp examination for evaluation of the red eye. Consensual photophobia, pain at a given distance of accommodation, and cell and flare are indicative of iritis. Funduscopic examination may provide evidence of posterior uveitis (vitreous, retinal, or choroid disease). Corneal staining and the Seidel test are useful for the diagnosis of keratitis and corneal perforation.

Findings on arthrocentesis will be consistent with nonseptic, inflammatory arthritis. A computed tomography scan of the brain or a lumbar puncture should be performed in patients with suspected focal intracranial or diffuse meningeal neurologic involvement. Two thirds of patients will have elevated cerebrospinal fluid protein, and half may have a predominantly mononuclear pleocytosis. These findings in some patients with extraneural sarcoid features may suggest the diagnosis of neurosarcoidosis.

Laboratory work will probably not help the EP make a diagnosis, but findings may include anemia of chronic disease, thrombocytopenia from splenomegaly, elevated serum calcium levels from granuloma-related abnormalities in calcitriol production, and nonspecific transaminitis as a result of asymptomatic hepatic granulomas.

Further work-up consisting of a tuberculin skin test, chest computed tomography scan, pulmonary function tests, echocardiography, angiotensin-converting enzyme levels, radionuclide imaging, endomyocardial biopsy for myocardial involvement, bronchoalveolar lavage, or endobronchial, transbronchial, mediastinal, or thoracoscopic biopsy may be considered for patients on an inpatient or outpatient basis with specialist consultation.

### TREATMENT

Two thirds of cases of sarcoidosis will resolve spontaneously within 2 years, and many patients can be managed by observation alone. Treatment focuses on suppression of granuloma formation with glucocorticoids and is reserved for individuals with functional impairment or chronic disease. Many patients with pulmonary involvement will not require ED treatment. Simple observation by a primary care physician

#### BOX 109.4 Differential Diagnosis of Sarcoidosis

**Most Common**
- Other granulomatous disease (tuberculosis, fungal, spirochetes, viral, parasitic)
- Environmental antigens
- Chemical antigens (silica, beryllium)
- Other autoimmune conditions (Sjögren syndrome)
- Human immunodeficiency virus

**Most Threatening**
- Primary cardiac arrhythmia, conduction deficit, cardiomypathy
- Neoplasm (pulmonary or lymphoma)
- Globe perforation
- Bacterial or aseptic meningitis

---

**Fig. 109.5** A, Stage I sarcoidosis: prominent hilar lymphadenopathy and normal lungs. B, Stage III sarcoidosis: interstitial infiltrate without hilar lymphadenopathy. (From Mason RJ, Broaddus VC, Murray JF, et al. Murray and Nadel’s textbook of respiratory medicine. 4th ed. Philadelphia: Saunders; 2004.)
on an outpatient basis for the development of treatable symptoms or abnormal findings on pulmonary function tests will suffice. Patients seen in the ED with significant dyspnea, functional impairment, and parenchymal disease noted on radiography are candidates for therapy with prednisone, 0.5 to 1 mg/kg/day, if bacterial, mycobacterial, fungal, and neoplastic processes can be excluded. Patients may need specialist consultation, hospital admission, or (at the very least) close outpatient follow-up. Depending on symptomatic response, doses can be tapered over a 6- to 12-month period by the patient’s primary physician.

Musculoskeletal complaints and erythema nodosum are best treated with NSAIDs. Patients with cardiac or neurologic involvement should first undergo standard ED management, with subsequent specialist consultation and consideration given to systemic treatment with glucocorticoids. Invasive interventions such as transvenous cardiac pacing or an intraventricular drain for obstructive hydrocephalus may be required. Ocular manifestations can be treated with topical cycloplegics and, after consultation with an ophthalmologist, topical corticosteroids. Suspected globe perforation as a result of severe keratitis warrants an ophthalmologic evaluation in the ED.

Weekly methotrexate and daily azathioprine are corticosteroid-sparing agents that can be prescribed by a pulmonologist or rheumatologist for steroid-dependent patients. Anti–tumor necrosis factor medication may be a future option in severe cases. In primary Raynaud phenomenon, the microstructure of distal vessels and permanent changes in the appearance of the extremity turns from white to blue. Paresthesias may be present. Subsequently, with increased flow, the digits become bright red in a phase termed reactive hyperemia. It is during this time of reperfusion that patients will have throbbing pain. Although the triphasic color changes are not always present, it is the predictable response to cold or stress that defines Raynaud phenomenon.

In primary Raynaud phenomenon, the appearance of the vasculature and the patient’s digits is normal between attacks.

In secondary Raynaud phenomenon, the symptoms are not always symmetric. Over time, there may be structural changes in distal vessels and permanent changes in the appearance of the patient’s digits.

### PATIENT DISPOSITION AND NEXT STEPS IN CARE

The EP should give first consideration to bacterial, mycobacterial, or fungal causes of the patient’s signs and symptoms. Lymphoma and other neoplastic processes are also potential diagnoses. If these entities can be excluded or if patients are known to have sarcoidosis, they may be discharged provided that they are minimally symptomatic. Oral prednisone can be prescribed if needed for control of symptoms. However, close outpatient primary care or rheumatology follow-up is mandatory in all cases.

Most patients with functional impairment and no known history of sarcoidosis will need to be admitted for evaluation of other infectious and neoplastic processes before a definitive diagnosis can be made and treatment started.

### PRIMARY RAYNAUD PHENOMENON

#### EPIDEMIOLOGY

Raynaud phenomenon is a vasospastic disorder marked by minute- to hour-long episodes of digital ischemia on exposure to cold or emotional stress. Up to 20% of the population may suffer from Raynaud phenomenon. Cases commonly involve women and occur in cooler environments.
A well-demarcated symmetric change in color occurs during an attack or can be precipitated by placement of the extremity in ice water. Fibrosis, pitting, or ulceration of the fingertips is indicative of the structural vascular and dermal changes in secondary Raynaud phenomenon. In the nail fold capillary examination, immersion oil is placed over the skin at the proximal end of the nail and an ophthalmoscope is used to denote normal-appearing capillaries. Abnormally tortuous, enlarged capillaries or a heterogeneous appearance may be indicative of Raynaud phenomenon secondary to scleroderma, idiopathic inflammatory myopathy, or another vascular disease.

Autoantibodies, cryoglobulins, and serum or urine protein electrophoresis to determine secondary causes of Raynaud phenomenon are not standard parts of the ED work-up.

**TREATMENT**

Patients should be instructed to avoid cold and stress, cease tobacco consumption, and wear warm clothing. Oral administration of nifedipine, 10 to 20 mg taken 30 minutes before exposure to cold, can minimize attacks.21 Alternatively, patients may take up to 60 mg/day divided into three doses. Once-a-day extended-release tablets are also available. Caution should be used in the elderly and those with cardiac and vascular disease. One study suggested that the angiotensin receptor blocker losartan (50 mg/day) outperforms nifedipine.22 Prazosin (1 to 2 mg three times daily) and topical nitrates are second-line agents for primary Raynaud phenomenon.23 Endothelin antagonists, phosphodiesterase inhibitors, and intravenous infusions of prostacyclin analogues are newer therapies for severe or secondary Raynaud phenomenon.22,24 Temporary relief of symptoms can be achieved by chemical sympathectomy via local or regional infiltration of an anesthetic. Surgical treatments, including palmar sympathectomy, thoracoscopic cervical sympathectomy, or arteriolyis (release of fibrotic adventitia), are last-line therapy.

**RED FLAGS**

Many connective tissue diseases have associated severe keratitis that may be complicated by globe perforation. Sarcoid granulomas can block the normal conduction system, with complete heart block being the most common manifestation. Consider sarcoidosis in patients with only bilateral hilar lymphadenopathy shown on a chest radiograph, especially if they are asymptomatic or have insidious pulmonary complaints.

Before diagnosing sarcoidosis, consider tuberculosis, histoplasmosis, community-acquired pneumonia, and lymphoma. Some of these patients will have to be admitted or treated empirically for an infectious process before a diagnosis can be secured via more extensive work-up. Patients who have functional impairment and no known history of sarcoidosis will need to be admitted for evaluation of other infectious and neoplastic processes before a definitive diagnosis can be made and treatment started.

Vasculitis Syndromes

Paul J. Allegretti and Keri Robertson

KEY POINTS

- A patient’s combined genetic predisposition and regulatory mechanisms control expression of the immune response to antigens.
- Negative test results for antineutrophil cytoplasmic antibodies do not exclude disease, nor do positive results indicate a specific syndrome.
- The combination of clinical, laboratory, biopsy, and radiographic findings usually points to a specific vasculitis syndrome.
- Definitive diagnosis of a vasculitic syndrome depends on demonstration of vascular involvement and may be accomplished by biopsy or angiography.
- Differentiation of primary and secondary vasculitis is essential because their pathophysiologic, prognostic, and therapeutic aspects differ.
- The diagnosis of vasculitis should be considered in any patient with febrile illness and organ ischemia without other explanation.

EPIDEMIOLOGY

In 1994, the Chapel Hill Consensus Conference named and defined the 10 most common forms of vasculitis according to vessel size (Box 110.1). This system is based on the fact that different forms of vasculitis attack different vessels.1,2 These criteria were established to differentiate specific types of vasculitis, but they are often used as diagnostic criteria. The vasculitic syndromes feature a great deal of heterogeneity and overlap, which leads to difficulty with regard to categorization.3 In addition, many patients display incomplete manifestations, thereby adding to the confusion. Emergency physicians should keep in mind the fact that nature does not always follow the patterns and artificial boundaries drawn by classification systems.4

TEMPORAL (GIANT CELL) ARTERITIS

Temporal, or cranial or giant cell, arteritis is a granulomatous large vessel vasculitis that affects the extracranial branches of the carotid artery, particularly the temporal artery. Females are affected two to four times more often than males, and the disorder usually occurs in patients older than 55 years. Its incidence is estimated to be 1 per 3000 individuals older than 50. Up to 59% of the time it is associated with polymyalgia rheumatica, which is characterized by pain and stiffness in the shoulders, neck, and pelvis, along with an elevated erythrocyte sedimentation rate (ESR).

TAKAYASU ARTERITIS

Takayasu arteritis (also referred to as aortic arch syndrome) is a granulomatous large vessel vasculitis that primarily affects the aorta, its branches, and the pulmonary and coronary arteries.1 This rare disease predominantly affects women in the 20- to 30-year-old age group and is more common in Asian and South American women. Mortality ranges from 10% to 75%.

POLYARTERITIS NODOSA

Polyarteritis nodosa is a multisystem necrotizing vasculitis of small- and medium-sized muscular arteries. Visceral and renal artery involvement is characteristic.3 The mean age at onset is 50 years, although it can occur at any age. Men, women, and racial groups are all affected equally. This rare disease affects fewer than 10 per 1 million persons worldwide.

KAWASAKI DISEASE

Kawasaki disease, also referred to as mucocutaneous lymph node syndrome, primarily affects children younger than 5 years. This acute systemic vasculitis is a febrile multisystem disease that is the leading cause of acquired heart disease in children in the United States.1 The disease occurs worldwide but predominates in Japan, Asia, and the United States.

WEGENER GRANULOMATOSIS

Wegener granulomatosis is a vasculitis of the upper and lower respiratory tract and kidneys. A systemic small vessel vasculitis is also involved. It may occur at any age but has a mean onset at 40 years of age. Wegener granulomatosis affects men and women equally and involves whites more commonly than blacks.

CHURG-STRAUSS SYNDROME

Churg-Strauss syndrome is a rare small vessel vasculitis manifested by fever, asthma, and hypereosinophilia.1 This disease is also referred to as allergic angiitis and granulomatosis.
particular when it affects the lungs. It is estimated that about 3 million people are affected worldwide, with an equal incidence between sexes. It is seen at all ages with a mean onset at 44 years of age.

**HENOCH-SCHÖNLEIN PURPURA**

Henoch-Schönlein purpura (anaphylactoid purpura) is a small vessel vasculitis that predominantly affects children and is characterized by palpable purpura, arthralgia, glomerulonephritis, and gastrointestinal symptoms. Though also seen in adults, 75% of cases occur in children younger than 8 years. It is more common than other vasculitides and affects males more frequently than females in a 2:1 ratio. It has a peak incidence in winter and spring and usually follows an upper respiratory tract infection.

**CUTANEOUS LEUKOCYTOCLASTIC VASCULITIS**

This disorder, also called hypersensitivity vasculitis or predominantly cutaneous vasculitis, involves small vessels of the skin and is the most common vasculitic manifestation seen in clinical practice. It has an incidence of 15 per million. In about 70% of cases, cutaneous vasculitis occurs along with an underlying process such as infection, malignancy, medication exposure, and connective tissue disease or as a secondary manifestation of a primary systemic vasculitis.

**BEHÇET SYNDROME**

Behçet syndrome is a multisystem inflammatory disease that affects vessels of all size. It is manifested as recurrent aphthous oral and genital ulcerations along with ocular involvement. Behçet syndrome is most prevalent at ages 20 to 35 years, with males suffering more severe disease.

**PATHOPHYSIOLOGY**

Vasculitis, also known as the vasculitides or the vasculitis syndromes, is a clinicopathologic process that results in inflammation and damage to blood vessels. Cell infiltration with inflammatory modulators causes swelling and changes in function of the vessel walls. This compromises vessel patency and integrity and leads to tissue ischemia, necrosis, and bleeding. Because most forms of vasculitis are not restricted to a certain vessel type or organ, the syndromes are broad and heterogeneous. Vasculitis is a systemic multorgan disease, so the findings may be dominated by a single or a few clinical organ manifestations.

Vasculitis can be separated into two broad categories. It may develop de novo as a primary manifestation of vessel inflammation without a known cause. Alternatively, it may be a secondary manifestation of an underlying disease or exposure to a drug. Distinction between primary and secondary vasculitis is essential because their pathophysiologic, prognostic, and therapeutic aspects differ.

Management of patients with the secondary forms of vasculitis needs to be directed toward the underlying disease process. The primary vasculitides, once thought to be uncommon, have proved to be much less rare than previously estimated, and awareness of the incidence and prevalence of all forms of vasculitis has recently increased. This chapter focuses on the primary or de novo vasculitides.

The pathophysiology of the vasculitis syndromes remains poorly understood, with variation between disease states contributing to the difficulty. It is also not clear why vasculitis develops in certain patients in response to antigenic stimuli and not in others; however, in each disease state, immunologic mechanisms play an active role in mediating blood vessel inflammation. Blood vessels can be damaged by three potential mechanisms (Box 110.2).
Immune complex deposition in vessel walls is the most well-known pathogenic mechanism of vasculitis and results in tissue damage from such deposition. Complement components are then activated and infiltrate the vessel walls. The immune complexes are phagocytosed and release damaging enzymes. As the condition progresses and becomes subacute, the vessel lumen may become compromised with subsequent tissue ischemia.

Antineutrophil cytoplasmic antibodies (ANCAs) develop in a large number of patients with systemic vasculitis, especially Wegener granulomatosis. These antibodies attack proteins in the cytoplasm of neutrophils. Two main types of ANCA are differentiated by the different targets of the antibodies: perinuclear ANCA (p-ANCA) attacks the enzyme myeloperoxidase, whereas cytoplasmic ANCA (c-ANCA) attacks the proteinase-3 enzyme.

The exact role of ANCA in the pathogenesis of vasculitis is unclear. Although a number of mechanisms have been proposed, confusion remains because vasculitis develops in many patients without ANCA, there is a lack of correlation with the quantitative value of ANCA and disease activity, and many patients in remission continue to exhibit high ANCA titers.

Pathogenic T-lymphocyte responses and granuloma formation may also be involved in damaging blood vessels. Delayed hypersensitivity and cell-mediated immune injury are the most common mechanisms in this category. Direct cellular toxicity or antibody-dependent cellular toxicity may also occur.

Two main factors are involved in the expression of a vasculitic syndrome: genetic predisposition and regulatory mechanisms associated with the immune response to antigens. Only certain types of immune complexes cause vasculitis, and the process may be selective for only certain vessel types. Other factors are also involved—for example, the reticuloendothelial system’s ability to clear the immune complex, the size and properties of the complex, blood flow turbulence, intravascular hydrostatic pressure, and the preexisting integrity of the vessel endothelium.

TEMPORAL (GIANT CELL) ARTERITIS

Giant cell arteritis is a panarteritis characterized by inflammatory mononuclear cell infiltration and giant cell formation in vessel walls. The intima proliferates and the internal elastic lamina fragments. Organ pathology results from ischemia related to the involved vessel derangement.

TAKAYASU ARTERITIS

The inflammation in Takayasu arteritis involves all vessel wall layers of medium- and large-sized vessels, especially the aorta and its branches. Panarteritis with inflammatory mononuclear cell infiltration and giant cells predominates. This results in scarring and fibrosis with disruption and degeneration of the elastic lamina. Narrowing of the vessel lumen (Fig. 110.1) follows with frequent thrombosis. Vessel dilation and the formation of aneurysms may also occur. Organ pathology results from ischemia.

POLYARTERITIS NODOSA

The inflammatory lesions associated with polyarteritis nodosa are segmental and involve the bifurcations and branches of arteries. Polymorphonuclear neutrophils infiltrate all layers of the vessel wall. The resultant intimal proliferation and degeneration of the vessel wall lead to vascular necrosis, which in turn results in thrombosis, compromised blood flow, and infarction of the involved tissues and organs. Characteristic aneurysmal dilations of up to 1 cm are common. Multiple organ systems are involved.

KAWASAKI DISEASE

The etiology of Kawasaki disease is unknown, but increasing evidence supports an infectious cause; however, whether the inflammatory response results from a conventional antigen or a superantigen continues to be debated. Although a strong predilection for the coronary arteries is seen, this vasculitis is systemic and may involve medium-sized arteries with corresponding manifestations. Initially, neutrophils are present in great numbers, but the infiltrate rapidly switches to mononuclear cells, T lymphocytes, and immunoglobulin A (IgA)-producing plasma cells. Inflammation involves all three layers of vessels. As in other vasculitides, there is typical intimal proliferation and infiltration of the vessel wall with mononuclear cells, which leads to beadlike aneurysms and thrombosis. Cardiomegaly, pericarditis, myocarditis, myocardial ischemia, and infarction may result.

WEGENER GRANULOMATOSIS

The pathology of Wegener granulomatosis involves a necrotizing vasculitis of small vessels with granuloma formation. The typical necrotizing granulomatous vasculitis in the lungs commonly leads to scarring, atelectasis, and obstruction. The upper airways also become inflamed, with necrosis and granuloma formation. Renal involvement takes the form of a focal and segmental glomerulonephritis that may become rapidly progressive. Few or no immune complexes are found on biopsy; the involvement of immunopathology is unclear. c-ANCAs develop in a large number of these patients, but this correlation is not clear. Besides the typical sinus, lung, and kidney involvement, other organs may be affected because Wegener granulomatosis is a systemic small vessel vasculitis.

CHURG-STRAUSS SYNDROME

The characteristic histopathologic features of Churg-Strauss syndrome include tissue infiltration by eosinophils, necrotizing small vessel vasculitis, and extravascular “allergic”
granulomas.\textsuperscript{1} The process can occur in any organ, but lung involvement predominates, and its association with asthma is strong. The combination of asthma, eosinophilia, granulomas, and vasculitis strongly suggests a hypersensitivity reaction as the triggering factor.\textsuperscript{7}

**HENCH-SCHÖNLEIN PURPURA**

Henoch-Schönlein purpura is an immune complex disease characterized by deposition of IgA-containing complexes. Suggested but unproved inciting antigens include upper respiratory infections, foods, drugs, insect bites, and vaccinations.\textsuperscript{3} All aspects of the disease are more serious when an adult is affected.

**CUTANEOUS LEUKOCYTOCLASTIC VASCULITIS**

The pathology predominantly involves small vessels, especially postcapillary venules. Acutely, neutrophils infiltrate the vessels, cause destruction, and result in nuclear debris—thus the term leukocytoclastic. As the process becomes more chronic, mononuclear cells and eosinophils become involved. Erythrocytes frequently extravasate and cause a classic palpable purpura, which is a hallmark of the disease.\textsuperscript{3}

**BEHÇET SYNDROME**

The main pathology in Behçet syndrome is vasculitis with a tendency to form venous thrombi.

### PRESENTING SIGNS AND SYMPTOMS

The diagnosis of many vasculitic syndromes is based more on the clinical findings than on laboratory results; therefore, a detailed history plus physical examination is an essential first step in the diagnosis.\textsuperscript{1} A high index of suspicion is necessary. The diagnosis should be considered in any patient with systemic febrile illness and signs of organ ischemia without a direct explanation. Non-specific symptoms such as weight loss, night sweats, and malaise are common. The vessels involved may correlate with the specific symptoms displayed.\textsuperscript{8}

**TEMPORAL (GIANT CELL) ARTERITIS**

Patients with temporal arteritis have local symptoms related to the arteries involved. Headache, scalp tenderness associated with the inflamed temporal artery (Fig. 110.2), jaw claudication, and visual disturbances are typical. Symptoms associated with polymyalgia rheumatica are frequently displayed. Constitutional symptoms such as fever, malaise, fatigue, anorexia, weight loss, arthralgias, and night sweats are also common. The most serious complication is ocular involvement as a result of ischemic optic neuropathy, which may lead to blindness; however, vision is usually avoided with proper treatment. A later complication may be an aortic aneurysm.\textsuperscript{9-11}

**TAKAYASU ARTERITIS**

Patients with Takayasu arteritis have ischemic symptoms of the involved vessels; such symptoms include visual problems, faint or absent pulses in the upper extremities, and myocardial, abdominal, and lower extremity ischemia. Differences in extremity blood pressure and bruits may also be present. Up to 40% of patients may experience systemic symptoms such as fever, malaise, night sweats, arthralgias, myalgias, weight loss, and anorexia. Death usually occurs from congestive heart failure or stroke. The course may be progressive and unremitting and become fulminant or may stabilize into remission.\textsuperscript{3}

**POLYARTERITIS NODOSA**

The most common symptoms of polyarteritis nodosa are fever, hypertension, myalgias, arthralgias, weight loss, malaise, and headache. Renal involvement evolves as flank pain, hematuria, renovascular hypertension, and renal failure. Skin lesions range from subcutaneous nodules to distal ischemia. Gastrointestinal manifestations include pain, malabsorption, bleeding, and perforation. Congestive heart failure secondary to coronary artery vasculitis may occur. A classic symptom is orchitis, which may occur in one third of male patients.\textsuperscript{4}

**KAWASAKI DISEASE**

The characteristic clinical features of Kawasaki disease are fever for at least 5 days, conjunctivitis, changes in the oral mucosa, a generalized rash, red palms and soles, indurative edema with subsequent skin desquamation, and cervical lymphadenopathy.\textsuperscript{5} The presence of five of these symptoms confirms the diagnosis. Of course, atypical cases with fewer symptoms occur.

**WEGENER GRANULOMATOSIS**

The characteristic manifestation of Wegener granulomatosis involves symptoms in the upper or lower airways (or both) for a prolonged period before the disease becomes systemic. Up to 90% of patients have sought medical attention for sinus or pulmonary problems earlier.\textsuperscript{1} Upper respiratory symptoms
include pain, purulent or bloody drainage, ulcerations, hoarseness, stridor, and deafness. Pulmonary findings are manifested as cough, dyspnea, chest pain, and hemoptysis, which may become severe. Pulmonary nodules, infiltrates, or cavitations may be seen on chest radiographs. Hypoxemia ensues when the lungs become affected.

Other manifestations include ocular inflammation ranging from conjunctivitis, episcleritis, and scleritis to retinal vasculitis and retroorbital masses. Skin lesions may appear as ulcerations, subcutaneous nodules, or purpura with necrosis. Central nervous system symptoms stem from infarction, cranial nerve neuropathy, and mononeuritis multiplex. Bowel perforation and bleeding may be symptoms of gastrointestinal involvement; pericarditis, coronary ischemia, and cardiomegaly may signal cardiac involvement. Vague symptoms such as malaise, weakness, arthralgia, fever, and anorexia are common.

Glomerulonephritis is present in 20% of patients at the time of diagnosis and develops in 80% at some point as the disease progresses. If not treated properly, renal involvement accounts for most mortality.

**CHURG-STRAUSS SYNDROME**

Symptoms such as fever, anorexia, malaise, and weight loss suggest a multisystem disease. Churg-Strauss syndrome has three identifiable phases. It begins with a prodrome of allergic rhinitis, nasal polyps, and asthma. The next phase includes peripheral eosinophilia and eosinophilic tissue infiltrates, especially in the lungs. The third phase is marked by a systemic vasculitis involving the lungs, heart, kidneys, central nervous system, and gastrointestinal tract. These phases may not occur in sequence and may not be seen in all patients.

The disease is best known for its severe and frequent exacerbations of asthma and relapsing vasculitis. The asthma associated with Churg-Strauss syndrome is not a classic allergic asthma that begins early in life; rather, it begins later in life around 35 years of age. It is severe, and patients frequently become steroid dependent.

**HENOCH-SCHÖNLEIN PURPURA**

The classic clinical picture of Henoch-Schönlein purpura includes four cardinal manifestations—palpable purpura, arthralgias, gastrointestinal involvement, and glomerulonephritis. The palpable purpura develops in nearly all cases and occurs most commonly over the buttocks and legs (Fig. 110.3). Polyarthralgia also develops in most patients. Gastrointestinal symptoms include abdominal pain with nausea, vomiting, diarrhea, constipation, and occasional gastrointestinal bleeding.

Renal disease is characterized by a mild glomerulonephritis with hematuria and proteinuria. Glomerulonephritis is seen in 20% to 50% of patients, with 2% to 5% progressing to end-stage renal disease.

**CUTANEOUS LEUKOCYTOCLASTIC VASCULITIS**

Clinically, besides purpura, patients may exhibit macules, papules, vesicles, bullae, subcutaneous nodules, or urticaria. The skin usually becomes pruritic and painful, and the lesions may progress to ulcers. Although the skin is predominantly involved, patients may exhibit systemic symptoms such as myalgias, fever, anorexia, and malaise. The course of the disease ranges from a brief single episode to multiple prolonged recurrences with infrequent progression to systemic vasculitis.

**BEHÇET SYNDROME**

Patients with Behçet syndrome have painful ulcers that occur as one ulcer or multiple ulcers; the ulcers last for 1 to 2 weeks and resolve without scarring. Besides oral ulcers, patients with Behçet syndrome may exhibit two or more of the following signs or symptoms: recurrent genital ulcers, skin lesions, eye lesions, and a positive pathergy test.

The genital ulcers resemble the oral ulcers. Skin lesions range from erythema nodosum and folliculitis to a general inflammatory exanthem. The ocular manifestations usually arise at onset of the disease but may develop later in the first few years. Iritis, posterior uveitis, retinal artery and vein occlusion, and optic neuritis may be seen. Hypopyon uveitis is rare but is pathognomonic of the disease. The ocular involvement may lead to blindness.

Other symptoms include mild arthritis of the lower extremity joints, gastrointestinal inflammation, and ulcerations. Central nervous system manifestations include meningocerebralitis, benign intracranial hypertension, multiple sclerosis–like symptoms, and psychiatric disturbances. Large venous or arterial thrombi or occlusions occur in 25% to 38% of patients. Pulmonary emboli are possible.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

**LABORATORY TESTS**

The complete blood count may reveal leukocytosis, normocytic normochromic anemia, and thrombocytosis. C-reactive protein (CRP) levels and the ESR may be elevated. Complement levels may be low. Because of renal involvement, urinalysis may reveal proteinuria or active sediment. Cerebrospinal fluid findings in patients with central nervous system vasculitis reveal elevated protein.

The ANCA associated with Wegener granulomatosis, first reported in 1985, is now an established entity in the evaluation of patients with suspected vasculitis. As with any diagnostic test, the predictive value of ANCA depends on the pretest probability of the disease. A negative test result does not exclude the disease, nor should the diagnosis of a vasculitic
syndrome be made or treatment initiated based on a positive ANCA titer alone. There have been reports of positive ANCA titers in patients with chronic infections and clinical features similar to systemic vasculitis. Therefore, caution is advised and testing for c-ANCA should not replace tissue biopsy.

**BIOPSY AND ANGIOGRAPHY**

Definitive diagnosis is dependent on demonstration of vascular involvement and may be accomplished by biopsy or angiography. Biopsy is preferred and should be directed toward tissue showing evidence of clinical involvement. Biopsy provides the distinct advantage of differentiating active from chronic disease. Such differentiation allows appropriate treatment.

Angiography is an excellent diagnostic modality when medium and large vessels are involved and visceral organ involvement is likely. This modality is the “gold standard” in the work-up of Takayasu arteritis, for which a full evaluation of the aorta is recommended. Angiography demonstrates luminal patency but provides no information about cellular or tissue status. Early vessel inflammation may still be present in a fully patent vessel. Conversely, vessel narrowing may also be due to fibrosis, not active disease. Therefore, clinical correlation is advised with each angiographic finding.

**NONINVASIVE IMAGING**

Noninvasive imaging modalities are useful in evaluating changes in the vessel wall not evident on angiography. They are associated with less morbidity than angiography and biopsy and have recently gained popularity in the serial evaluation and detection of early disease in patients with vasculitis.

High-resolution ultrasonography is an efficient, noninvasive, and inexpensive method of monitoring known cases of vasculitis. An example of clinical application is the evaluation of stenotic segments of the carotid arteries. Progression—and hopefully resolution—with treatment of this pathology can also be monitored with ultrasonography. The fact that it cannot detect disease in all vessels, particularly the pulmonary, thoracic, and abdominal visceral vessels, limits this modality.

Computed tomography (CT) can be useful to detect vessel wall thickening, especially in early Takayasu arteritis. CT angiography, high-resolution CT, and electron beam CT have all improved diagnostic outcomes. CT may also be used to evaluate sinus pathology or pulmonary lesions in patients with Wegener granulomatosis. To exclude infection, sarcoidosis, and malignancy, biopsy should follow CT when evaluating these lesions.

Magnetic resonance imaging (MRI) can be used to assess vessel wall thickening and has the advantage of axial, sagittal, and coronal plane views. Magnetic resonance angiography (MRA) correlates well with findings on CT angiography when evaluating the aorta or renal arteries. Further studies are needed before MRI or MRA can be considered first-choice diagnostic tools.

Positron emission tomography measures glucose metabolism in tissues. Increased glycolysis is seen in inactivated leukocytes and macrophages and is a hallmark of inflammation in certain vasculitides, especially giant cell arteritis.

Single-photon emission computed tomography (SPECT) uses multiplanar nuclear imaging to investigate abnormalities in perfusion, especially when evaluating central nervous system vasculitis. Clinical correlation is necessary because perfusion defects may not distinguish vasculitis from entities such as vasospasm, thromboembolism, atherosclerosis, and malignant hypertension. SPECT may also be useful in evaluating the coronary arteries in patients with Kawasaki disease.

**DIAGNOSIS OF SPECIFIC VASCULITIC SYNDROMES**

**Temporal (Giant Cell) Arteritis**

Classic laboratory manifestations include an elevated ESR and CRP. Normochromic anemia and thrombocytosis secondary to the chronic inflammation are common. Liver function abnormalities, particularly an elevated alkaline phosphatase level, are common.

The diagnosis can be determined clinically because of the classic scenario of headache, fever, anemia, and an elevated ESR. Temporal artery biopsy is confirmatory. Because involvement of the vessel may not be contiguous, several separate biopsies may be needed. Color duplex ultrasonography, angiography, or MRI may play a role in making the diagnosis. A rapid clinical response to treatment also confirms the diagnosis.

**Takayasu Arteritis**

Laboratory findings during active disease include an elevated ESR and increased CRP levels. Angiography demonstrates stenosis, occlusion, dilation, and aneurysms of the aorta and its branches. The entire aorta should be visualized to fully appreciate the spectrum of this disease. Spiral CT angiography and MRA have been shown to be useful.

The diagnosis should be suspected in any young woman with the systemic signs and symptoms previously described and with any blood pressure or pulse discrepancies or bruits. Establishment of the diagnosis must then be achieved by radiologic procedures.

**Polyarteritis Nodosa**

No diagnostic serologic tests are available for polyarteritis nodosa, and laboratory findings are nonspecific; the ESR, CRP, and leukocytes are elevated. Normochromic anemia is present and is indicative of chronic disease. The diagnosis may be achieved by biopsy demonstrating histologic necrotizing inflammation in the arteries. If biopsy is not possible, angiography demonstrating microaneurysms, stenosis, or sequential narrowing and dilation suggests the diagnosis.

**Kawasaki Disease**

Echocardiography and angiography confirm the cardiac complications and vasculitis. Laboratory findings include elevated leukocytes, platelets, ESR, and CRP.

Although the disease is generally benign and self-limited, coronary artery aneurysms occur in 20% to 30% of patients, usually during the third or fourth week as convalescence ensues. The presence of four symptoms along with coronary artery aneurysms is diagnostic. The case fatality rate secondary to coronary artery aneurysm is 0.5% to 2.8%.

**Wegener Granulomatosis**

Laboratory findings include an elevated ESR and CRP, anemia with leukocytosis, thrombocytosis, and positive tests for ANCA, which is seen especially when the kidneys are affected.
The diagnosis is made by biopsy demonstrating necrotizing granulomatous vasculitis with an aggregation of neutrophils in nonrenal tissue. Renal biopsy reveals focal, segmental, necrotizing, crescentic glomerulonephritis. Biopsy findings coincide with the characteristic clinical findings of sinus, pulmonary, and renal symptoms. Although the use of ANCA testing is only adjunctive, its specificity is 90% for Wegener granulomatosis if active glomerulonephritis is present.

**Churg-Strauss Syndrome**
Classic laboratory findings include leukocytosis with notable eosinophilia, anemia, and elevated ESR and CRP. The diagnosis is confirmed via biopsy in a patient with the characteristic clinical manifestations.

**Henoch-Schönlein Purpura**
Laboratory studies are nonspecific and may reveal a mild leukocytosis and occasional eosinophilia. Serum IgA levels are elevated in 50% of patients. The diagnosis remains a clinical diagnosis based on the characteristic findings. A skin biopsy is occasionally necessary for confirmation and reveals leukocytoclastic vasculitis with IgA immune deposition. Renal biopsy better serves as a prognostic indicator.

**Cutaneous Leukocytoclastic Vasculitis**
Laboratory values are usually within normal limits, including ESR and CRP levels. Mild leukocytosis and eosinophilia may be present. Laboratory studies should be used primarily to rule out the presence of systemic vasculitis. Minimal to no signs of inflammation should be found. The diagnosis is made by skin biopsy and by carefully ruling out systemic disease or exogenous reasons for the vasculitis. The clinical and histopathologic appearance of the lesions is indistinguishable from the cutaneous manifestations of the systemic vasculitides; therefore, the diagnosis should be one of exclusion after other causes have been ruled out. Only then can the disorder be called true cutaneous leukocytoclastic vasculitis or idiopathic cutaneous vasculitis.

**Behçet Syndrome**
Laboratory findings indicate nonspecific inflammation such as leukocytosis and elevated ESR and CRP levels. Half of patients are found to have autoantibodies to human oral mucous membranes. The diagnosis is based on the clinical findings of recurrent aphthous oral ulcerations.

### TREATMENT
The combination of clinical, laboratory, biopsy, and radiographic findings usually points to a specific syndrome (Table 110.1). Therapy should then be initiated as appropriate. If the vasculitis is associated with a specific disease such as neoplasm, infection, or connective tissue disease, the underlying disease should be treated. If the syndrome resolves, no further treatment is needed. If the syndrome persists, treatment of vasculitis should be initiated. Likewise, if an offending antigen is recognized, it should be removed if possible. No further treatment is needed if the syndrome resolves; however, if the syndrome continues, treatment must be initiated. Treatment initiated for a primary vasculitis syndrome should focus on using the most effective and least toxic options based on published experience.

**TEMPORAL (GIANT CELL) ARTERITIS**
Treatment should commence immediately and not be delayed by diagnostic procedures. Administration of 40 to 60 mg of prednisone daily for 1 month is followed by a taper to 7.5 to 10 mg daily. This should be continued for 1 to 2 years to prevent relapse. Aspirin, 81 mg daily, has been shown to reduce cranial ischemic complications and should be given to patients without contraindications. Clinical symptoms and the ESR are used to monitor disease activity.

**TAKAYASU ARTERITIS**
Treatment consists of the combination of 40 to 60 mg/day of prednisone and aggressive surgical or angiographic procedures directed toward stenotic vessels. This approach corrects hypertension caused by renal artery stenosis, improves blood flow in ischemic vessels, and decreases risk for stroke, thereby resulting in decreased morbidity and improved survival.

**POLYARTERITIS NODOSA**
Combination therapy consisting of prednisone (1 mg/kg/day) and cyclophosphamide (2 mg/kg/day) has resulted in a long-term remission rate of 90% after therapy has been discontinued. Glucocorticoids may be used alone in mild cases.

**KAWASAKI DISEASE**
Treatment consists of high-dose intravenous gamma globulin (2 g/kg infused over a 10-hour period) administered concurrently with aspirin (80 to 100 mg/kg/day for 2 weeks followed by 3 to 5 mg/kg/day for several more weeks). Early therapy has proved beneficial in reducing coronary artery abnormalities.

**WEGENER GRANULOMATOSIS**
Administration of cyclophosphamide (2 mg/kg/day) combined with prednisone (1 mg/kg/day) has proved to be the most successful therapy. Reported results are complete remission in 75%, a survival rate of 80%, and marked improvement in 91%. Though very effective, cyclophosphamide may be associated with severe bone marrow toxicity. Leukocytes must be monitored closely and kept at a level above 3000 mcg.

Full-dose cyclophosphamide therapy should be continued for 1 year after remission and then tapered off. Prednisone therapy may be changed to alternate-day administration after 1 month and then tapered off by 6 months. Methotrexate has shown some success in patients who cannot tolerate cyclophosphamide.

**CHURG-STRAUSS SYNDROME**
The most effective therapy is prednisone (1 mg/kg/day). The vasculitis usually remits more readily than the asthma, which may remain moderate to severe and thus make discontinuation of prednisone therapy difficult. Cyclophosphamide at 2 mg/kg/day may be added to the prednisone in patients not responsive to prednisone alone.

**HENOECH-SCHÖNLEIN PURPURA**
Although renal failure is the most common cause of death, Henoch-Schönlein purpura usually resolves without therapy. In general, the disease is self-limited with an excellent prognosis for full recovery in as little as a few weeks.
However, when required, prednisone at 1 mg/kg/day is effective in lessening tissue edema, arthralgias, and abdominal pain. The dose should be tapered as the symptoms abate. Glucocorticoids have no proven benefit on skin and renal involvement and have not been shown to shorten the course of the disease or prevent relapse.3

**CUTANEOUS LEUKOCYTOCLASTIC VASCULITIS**

If an underlying process is discovered to be the cause of the cutaneous symptoms, treatment should be aimed at the underlying process. If an exogenous agent is the culprit, removal of it usually results in remission of the skin process. If true cutaneous leukocytoclastic vasculitis is determined to be the etiology, glucocorticoids administered at a dosage of 1 mg/kg/day have proved effective.5

Frequently, the disease is self-limited; otherwise, it generally responds very rapidly to steroid therapy. Some symptomatic agents may be used on occasion, such as antihistamines, nonsteroidal antiinflammatory drugs, and colchicine. In the rare scenario in which glucocorticoids are not effective, cytotoxic agents such as methotrexate, azathioprine, and...
cyclophosphamide may be used, but these drugs should be reserved for severe cases.

**BEHÇET SYNDROME**
Treatment is based on disease manifestations. Oral and skin lesions respond well to topical glucocorticoids, dapsone, or colchicine. Thrombophlebitis is treated with aspirin. Ocular and central nervous system manifestations require aggressive treatment with immunosuppressive agents such as glucocorticoids, azathioprine, or cyclosporine.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

**TEMPORAL (GIANT CELL) ARTERITIS**
The prognosis is good; the majority of patients go into remission and remain in remission after discontinuation of steroids. Patients with severe disease or impending vision loss should be hospitalized and given high-dose intravenous steroids.

**TAKAYASU ARTERITIS**
Hospital admission for diagnostic testing and treatment should be considered for suspected cases. It is the best practice but not always possible to control the vascular inflammation with prednisone before any surgical procedures.

**POLYARTERITIS NODOSA**
Discharge home with follow-up is appropriate except in patients with evidence of end-organ failure.

**KAWASAKI DISEASE**
Except for rare fatal cardiac complications, the prognosis is good, typically with full recovery. Children in whom aneurysms develop require close follow-up after discharge, and some patients with severe disease may need long-term anticoagulation.

**WEGENER GRANULOMATOSIS**
Outpatient management is appropriate except in patients with advanced end-organ involvement. On achievement of remission, long-term follow-up is essential. Up to 50% of patients have one or more relapses. With close follow-up and immediate reconstitution of therapy, induction of remission is almost always a success. In many patients, especially those with multiple relapses, some degree of long-term morbidity develops, such as renal insufficiency, tracheal stenosis, hearing loss, or sinus impairment. Aggressive prompt therapy during the initial manifestation of the disease, as well as during relapses, helps diminish the degree of chronic morbidity.

**CHURG-STRAUSS SYNDROME**
Outpatient management is appropriate except in patients with advanced end-organ involvement. The prognosis of untreated patients is a 25% 5-year survival rate, which improves to 50% with proper treatment.

**HENOCH-SCHÖNLEIN PURPURA**
Patients with Henoch-Schönlein purpura who have severe abdominal pain, significant gastrointestinal bleeding, or marked renal insufficiency may require hospitalization.

**CUTANEOUS LEUKOCYTOCLASTIC VASCULITIS**
This disorder may be managed on an outpatient basis.

**BEHÇET SYNDROME**
Treatment may be managed on an outpatient basis unless ocular or central nervous system manifestations are evident.

**TIPS AND TRICKS**
Although antineutrophil cytoplasmic antibodies (ANCAs) are quite common in patients with vasculitis, their role is not clear. ANCA testing may actually confuse the diagnostic picture when results are negative in a patient with clinical vasculitis, when there is a lack of quantitative correlation with disease activity, and when high titers are found in patients whose disease has fallen into remission. Vision loss associated with temporal arteritis may be prevented with immediate and proper treatment. In patients with any signs of this complication, treatment must not be delayed because permanent vision loss may ensue. Patients with Wegener granulomatosis often have prolonged signs and symptoms of upper or lower airway dysfunction, or both. Ninety percent of these patients have previously been evaluated for sinus problems that became chronic. A high index of suspicion is required. The asthma associated with Churg-Strauss syndrome is a severe condition that usually begins when the patient is about 35 years of age. With treatment, the vasculitis commonly subsides much more readily than the asthma.

REFERENCES

The male genitalia is composed of the penis, with paired erectile bodies and the penile urethra, and the scrotum, which encases the testis, epididymis, and spermatic cord bilaterally. Beneath the scrotal skin is the superficial scrotal (dartos) fascia (which is contiguous with the fascia of the abdomen, known as the fascia of Scarpa), the perineal (Colles) fascia, and the penile (dartos) fascia. The spermatic fascia lies beneath the dartos fascia; it has three layers, with the middle layer forming the cremaster muscle. These anatomic layers may provide a conduit for the rapid spread of infection.

The fibrous capsule of the tunica albuginea surrounds each testis. A break in the integrity of the tunica albuginea represents a “ruptured” testicle, which can be caused by blunt trauma. External to the testicular parenchyma and tunica albuginea is the tunica vaginalis, which envelopes each testicle and fastens it to the posterior scrotal wall.

The gubernaculum, or scrotal ligament, anchors each testis inferiorly and provides additional stability. The tunica vaginalis consists of both visceral (contiguous with the tunica albuginea) and parietal (contiguous with the deep spermatic fascia) layers, with an interposed potential space. A lack of firm attachment of the testicle to the posterior scrotal wall makes the testis prone to rotation in a horizontal plane about the spermatic cord, a condition termed testicular torsion.

The testicular artery originates from the aorta just below or directly from the renal artery. The spermatic cord contains both the blood supply to each testicle via the gonadal vessels and the vas deferens. Interruption of blood flow to the testis by twisting of the spermatic cord can lead to rapid ischemia and subsequent infarction of the affected testicle in cases of testicular torsion.

The appendix testes are embryologic remnants with no known physiologic function. These appendages are prone to torsion as well, which can lead to localized, self-limited necrosis. It results in clinical findings that may be confused with testicular torsion.

The epididymis adheres closely to the posterolateral aspect of each testis. It is involved in promoting sperm maturation and motility. The appendix epididymis is an embryologic remnant typically attached to each epididymis. These too are prone to torsion.

The vas deferens is a tubular structure involved in sperm transit; it extends from the epididymis distally to the prostatic portion of the urethra proximally.

The penis consists of the corpora cavernosa (erectile bodies) and the corpus spongiosum, which surrounds the urethra. In uncircumcised males, the retractile penile foreskin covers the glans. The potential constricting effect of proximally retracted foreskin may lead to paraphimosis. In paraphimosis, venous engorgement of the glans and edema resulting from constriction can potentially progress to arterial compromise and necrosis of the distal end of the penis. Each corpus cavernosum is surrounded by the tunica albuginea as well.

Priapism is a pathologic condition defined as the presence of a persistent erection lasting longer than 4 hours in the
absence of sexual desire or stimulation. It most frequently results from engorgement of the corpora cavernosa with stagnant blood (termed low-flow priapism). Box 111.1 lists several causes of low-flow priapism.

High-flow priapism is rare and is caused by the development of traumatic arterial-cavernosal fistulas, which results in the accumulation of oxygen-rich blood in the corpora.

**PRESENTING SIGNS AND SYMPTOMS**

Genitourinary complaints are often influenced by patient embarrassment and apprehension, especially in children and adolescents. Complaints of abdominal pain, fever, or nausea may be offered by the patient, but information about scrotal or penile issues may be withheld. It is important to speak with the patient alone to maximize patient disclosure, privacy, and confidentiality.

**ACUTE SCROTAL PAIN**

One of the most challenging aspects of male genitourinary complaints is that a wide variety of clinical conditions may all be manifested as acute, unilateral (or bilateral) pain and swelling of the scrotum. Although the differential diagnosis for such symptoms is extensive, threats to life and fertility need to be excluded. Testicular torsion, Fournier gangrene, and an incarcerated or strangulated inguinal hernia are surgical emergencies. The vast majority of acute testicular pain, however, can be attributed to one of three diagnostic entities: testicular torsion, epididymitis, or appendage torsion (Table 111.1).

**HISTORY**

Pain may be due to structures within or adjoining a particular region or may be referred from other areas. Delineation of the source of the pathology is essential. For example, pain from abdominal aortic aneurysms, renal colic, and pyelonephritis can radiate to the testicles.

**ONSET OF SYMPTOMS**

Pain that begins abruptly and is severe suggests testicular torsion. Intermittent severe pain can signal intermittent torsion. Twisting of the spermatic cord leads to rapid diminution of blood supply to the affected testicle and resultant ischemic pain. This is in contrast to the more indolent pain of epididymitis, a gradually progressive inflammatory process. Patients with long-standing inguinal hernias often complain of isolated genital pain of prolonged duration. However, patients with an incarcerated (cannot be reduced) or strangulated hernia (with ischemic or infarcted, herniated bowel) may experience more acute pain.

Testicular torsion may accompany a report of minor scrotal trauma. Testicular torsion can also take place in the absence of such events and may even occur during sleep.

**CHARACTER OF SYMPTOMS**

The distinction between constant progressive and intermittent colicky pain is potentially useful in the diagnosis of acute scrotal pain. Constant and progressive pain typically results from progressive inflammatory processes such as epididymitis. Patients may exhibit pain with ambulation and other movements as a result of the inflammation. Intermittent and colicky pain is more consistent with rapid onset and offset conditions, as occurs with twisting of the spermatic cord, either suddenly or intermittently.

Patients with testicular torsion often complain of severe pain as a consequence of ongoing testicular ischemia. Pain resulting from inflammatory processes (epididymitis) may be relieved temporarily by rest and scrotal elevation with a supportive undergarment such as a jockstrap. Similarly, the inflammatory pain is often exacerbated by movement, thus leading a patient to remain still. Alternatively, patients exhibiting the colicky symptoms of testicular torsion may write in pain as they try (and often fail) to find a position of comfort. These symptoms are generalizations and, when considered alone, lack high sensitivity or specificity.

**ASSOCIATED SYMPTOMS**

Patients with nausea or emesis are less likely to have torsion of an appendage or simple, uncomplicated epididymitis. It is more likely that substantial pathology is present. Patients

is useful. It is important to assess for lower abdominal tenderness or a mass, which potentially signals acute appendicitis, inguinal hernia, genitourinary malignancy, abdominal trauma, or an advanced perineal infection such as Fournier gangrene. Tenderness at the costovertebral angle may be present with retroperitoneal processes such as pyelonephritis, renal colic, and an expanding or ruptured abdominal aortic aneurysm.

**GENITAL EXAMINATION**

The genitalia should be examined while the patient is both standing and lying supine. Caution should be used when examining a standing patient because some males experience a strong vagal response to scrotal (or prostate) stimulation that can lead to presyncope or syncope. In addition, examination of the testicles and epididymis may cause significant discomfort, even in the absence of pathology. Because many patients have unilateral pain, the unaffected side should be examined first. This serves as a control and helps gain the trust of the patient.
Visual examination of the genitals may reveal cutaneous rashes or lesions, abnormal testicular symmetry or position, edema evident by loss of the scrotal skin folds, and masses. Key visual features of testicular torsion include a high-riding and transverse lie of the affected testicle.\textsuperscript{2,4,7}

It is important to look for evidence of scrotal and perineal erythema or ecchymoses, particularly in older patients with scrotal pain. This may be the only clue to the presence of Fournier gangrene, which often affects diabetics and other immunocompromised individuals. However, a prominent feature of necrotizing fasciitis is significant pain in the absence of pronounced physical findings.

A digital rectal examination provides information regarding the prostate and the prostatic portion of the urethra. Exquisite prostate tenderness may indicate acute prostatitis. Firmness and enlargement of the prostate are typically signs of benign prostatic hypertrophy; nodularity is concerning for prostatic carcinoma. These conditions may be accompanied by variable genitourinary symptoms.

**ACUTE PENILE PAIN**

Patients with low-flow priapism often complain of an exquisitely painful and prolonged erection. Stagnant, oxygen-poor, acidic blood accumulates in the corpora and results in ischemic pain. Ischemia may lead to irreversible cellular damage, permanent fibrosis, and impotence if the duration of the pathologic erection is prolonged. Of note, the use of oral erectile dysfunction treatments such as sildenafil (Viagra) have only rarely been associated with priapism.\textsuperscript{1}

Patients with high-flow priapism often complain of a persistent, yet painless erection that is caused by continuous inflow of well-oxygenated blood through traumatic arterial-cavernosal fistulas.

Paraphimosis classically develops in uncircumcised males when the proximally retracted foreskin acts as a constricting band on the mid to distal portion of the penile shaft. Disruption of venous drainage by the constricting foreskin leads to a vicious cycle of progressive glans edema. Progressive glans edema will eventually cause arterial compromise, ischemic pain, glans necrosis, and gangrene. Penile paraphimosis should always be replaced after retraction during examination or placement of a urethral catheter to avoid the development of iatrogenic paraphimosis.

Penile constriction analogous to paraphimosis can also occur. Objects constricting the penile shaft lead to the same pathophysiologic derangements seen with paraphimosis. These objects may be placed intentionally (e.g., string, metal, rubber rings), or the constriction may occur sporadically, as in the case of a hair tourniquet. Hair tourniquets may be very difficult to diagnose because the offending hair is nearly invisible within an edematous coronal sulcus. An occult hair tourniquet should be considered along with testicular torsion in a male infant with inconsolable crying. Removal of the offending hair from the coronal sulcus can be difficult. It has been reported that over-the-counter hair removal products, including depilatories such as Nair, have been used successfully for the removal of digital (finger, toe) hair tourniquets, thus suggesting its utility for penile hair tourniquets as well.\textsuperscript{9}

**SEXUALLY TRANSMITTED DISEASES**

Genital infections that are likely to cause acute symptoms can generally be divided into diseases characterized by genital ulceration (e.g., genital herpes) and diseases causing penile discharge (urethritis).

Among the many infections that can cause genital ulceration, genital herpes, syphilis, and chancroid are the most common in the United States; genital herpes is the most prevalent.\textsuperscript{11}

Primary or recurrent genital herpes may be manifested as severe pain, pruritus, or burning localized to the penis, scrotum, rectum, or elsewhere in the perineum. The typical pattern of multiple grouped vesicular or ulcerative lesions may be absent entirely in many acutely infected persons, however, thus rendering the diagnosis elusive.

Syphilis is a systemic disease caused by Treponema pallidum. Patients with syphilis may seek treatment for signs or symptoms of primary infection, which is often a painless ulcer (chancre) at the infection site, typically on the head or distal shaft of the penis.

Chancroid is caused by Haemophilus ducreyi and is classically manifested by the combination of a painful ulcer and tender inguinal adenopathy.

Diagnosis of any of these ulcerative infections is frequently inaccurate when based on the history and physical examination alone.\textsuperscript{11} Therefore, evaluation of all patients with genital ulcers should include a serologic test for syphilis and a diagnostic evaluation for genital herpes. Testing for H. ducreyi should be performed in settings where chancroid is prevalent.
Findings on urinalysis suggestive of a urinary tract infection may be present in cases of urethritis or epididymitis. Urethritis is typically characterized by discharge of mucopurulent or purulent material, with or without accompanying dysuria or urethral pruritus. The principal bacterial pathogens of proven clinical importance in men who have urethritis are *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Asymptomatic infections are common as well.

### SPECIAL SIGNS AND TECHNIQUES

Several adjuncts to the traditional examination are commonly used when assessing the male genitourinary tract.

An intact ipsilateral cremasteric reflex is frequently used, though imperfect, for excluding the diagnosis of testicular torsion.12-14 This reflex is elicited by stroking the ipsilateral inner aspect of the thigh, which results in a reflexive elevation of the testicle through contraction of the cremaster muscle. Absence of this reflex is nonspecific in that healthy individuals may lack the reflex altogether, particularly boys in the first few years of life.15 Of note, there have been several published reports of testicular torsion with an intact cremasteric reflex.16-18

The Prehn sign, or relief of pain with scrotal elevation, was previously thought to help in differentiating epididymitis from testicular torsion (the latter condition having no improvement in symptoms with elevation). However, this sign has been found to be unreliable in distinguishing these two disorders, and its use for this purpose should be abandoned.

In appendage torsion, the “blue dot sign” is pathognomonic. Appendage torsion is most common in the prepubescent age group, and the infarcted appendage (the blue dot) is seen through thin, non–hormonally stimulated prepubertal skin.

Scrotal transillumination may be performed in cases of suspected hydrocele. The scrotal contents should become transilluminated when filled with light-transmitting fluid, as is the case with a hydrocele. However, transillumination is neither sensitive nor specific for the diagnosis of hydrocele, and the results should be interpreted with caution.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Most routine diagnostic aids, such as blood work or urinalysis, add little to distinguish the emergency causes of acute scrotal pain. Rather, they may actually worsen the outcome of patients by causing delays in consultation and therapeutic action. If the history and physical examination suggest the diagnosis of testicular torsion, urology (or general surgery) services should be consulted and plans made for immediate surgical exploration without delay. A patient of appropriate age with the classic history and examination findings of testicular torsion does not require any diagnostic tests. In low-risk or unclear circumstances, a confirmatory imaging study is indicated, and ultrasonography is typically used for this purpose.

In cases of Fournier disease, a delay in recognition and surgical débridement can be life-threatening. Early consultation plus administration of broad-spectrum antibiotics is indicated in all suspected cases. However, prompt surgical débridement remains the definitive treatment.11,20

### LABORATORY TESTING

Any patient encountered in the emergency department (ED) with penile discharge should be assumed to have infectious urethritis. Centers for Disease Control and Prevention (CDC) guidelines recommend testing to determine the specific cause.11 Urine polymerase chain reaction testing for *N. gonorrhoea* and *Chlamydia* infection is available at most institutions. Urine samples to test for urethritis should be collected at the initiation of the urine stream without cleansing of the glans; midstream collection and glans cleansing are necessary for urine culture in patients with suspected cystitis or pyelonephritis. If polymerase chain reaction testing is unavailable, swabs of the lining of the distal 1 to 2 cm of the penile urethra are necessary for testing.

An elevated systemic white blood cell count may be present in cases of inflammation, as well as infection, but does little to narrow the differential diagnosis—awaiting results could delay definitive management. Patients with advanced infections (e.g., scrotal abscess, epididymoorchitis, Fournier gangrene) may have a markedly elevated white blood cell count or granulocyte predominance, but the test lacks sufficient sensitivity and specificity.

### ULTRASONOGRAPHY

Ultrasound visualization is the most useful diagnostic modality for the evaluation of genitourinary complaints. Color flow duplex Doppler ultrasound is generally helpful in distinguishing potential causes of acute scrotal pain. The classic finding suggestive of testicular torsion is diminished intratesticular blood flow. In addition, examination of the spermatic cord with high-resolution gray-scale sonography may reveal kinking of the spermatic cord.21 In epididymitis, perfusion is normal or increased because of the effects of inflammatory mediators on local vascular beds.

Ultrasonography may also identify an infarcted appendage, hydroceles, hematocoeles, varicoceles, hernias, tumors, abscesses, and gonadal vasculitis, among other conditions. In patients with testicular trauma, ultrasonography may identify disruption of the tunica albuginea, which signals testicular rupture. Doppler blood flow studies can measure the adequacy of blood flow. Absent blood flow means that traumatic torsion or vascular injury has occurred.

Ultrasound evaluation of acute scrotal problems has its limitations. Surgical scrotal exploration remains the only definitive diagnostic modality in assessing for testicular torsion. When is the risk low enough to safely send a patient home following “normal” ultrasound findings? Even though some series have found ultrasound to be unreliable, other larger series have reported a negative predictive value approaching 97%.25 However, if ultrasound is nondiagnostic of testicular torsion and the clinical picture is still concerning, emergency surgical consultation is prudent.

### COMPUTED TOMOGRAPHY

Computed tomography may be helpful in assessing the extension or depth of a genitourinary abscess or Fournier disease and may aid in the search for coexisting injuries or foreign bodies in the evaluation of a trauma patient.
TREATMENT

ANALGESIA
Analgesia should be administered parenterally in most cases because of the significant pain associated with the majority of the aforementioned conditions. Analgesia should not be withheld pending consultation. If the likelihood of surgical intervention is low or if the pain is mild on arrival, a trial of oral medications can be offered. The agents used most frequently are narcotic analgesics, nonsteroidal antiinflammatory drugs, and acetaminophen.

MANUAL TESTICULAR DETORSION
In the case of prolonged time until definitive treatment, manual testicular repositioning may be attempted. Because testicular torsion usually occurs in a lateral to medial fashion, detorsion is often accomplished by rotation of the affected testicle from medial to lateral. However, medial to lateral torsion occurs up to a third of the time. The end point of the detorsion procedure is relief of pain.

Emergency Surgery for Testicular Torsion
Testicular salvage rates are time dependent; more than 90% of testicles are salvaged if detorsion occurs within 6 hours after the onset of symptoms, whereas the salvage rate is less than 20% when treatment is delayed by more than 24 hours. Immediate surgical consultation is important when testicular torsion is likely.

SCROTAL ELEVATION
Elevation of the scrotum may be beneficial in patients with inflammatory conditions such as epididymitis. It is easily accomplished with the use of a towel roll or supportive undergarments, such as a jockstrap. In addition, ice may reduce edema and provide mild symptomatic relief.

ANTIBIOTIC THERAPY
Antimicrobial agents are indicated in cases of suspected or proven infection. Early broad-spectrum antibiotic therapy is imperative in any patient with suspected Fournier disease. Recommended empiric intravenous antimicrobials include ampicillin-sulbactam plus clindamycin and ciprofloxacin or clindamycin plus an aminoglycoside in individuals with known penicillin hypersensitivity. The addition of vancomycin to either regimen for expanded gram-positive coverage is reasonable.

SEXUALLY TRANSMITTED DISEASES
Because timely follow-up counseling and treatment of patients with abnormal test results are impractical in the ED setting, empiric antimicrobial treatment of the probable pathogens should be initiated (Table 111.2), and counseling regarding notification of the patient’s sexual contacts should be underscored. Patients should wear a condom during intercourse following treatment for at least 1 week after the symptoms have resolved, although the CDC recommends consistent use of latex condoms to reduce the risk for many sexually transmitted diseases, including human immunodeficiency virus.

Antibiotics are the cornerstone of therapy for epididymitis. Antimicrobial selection is guided by patient demographics: sexually active males younger than 35 years are treated presumptively for N. gonorrhoeae and C. trachomatis with intramuscular ceftriaxone and oral doxycycline, respectively. Broader coverage should be considered for coliform and fungal species in males who engage in anal insertive intercourse (with presumed gonorrhea and Chlamydia coinfection).

Patients older than 35 years are treated with agents that cover the common urinary pathogens. This age distinction, however, is arbitrary and variability exists.

Distinction between urethritis with or without accompanying epididymitis is important in patients with penile discharge. When accompanying epididymal pain or tenderness is present, the duration of antimicrobial treatment is lengthened because epididymitis represents a more advanced stage of reproductive tract disease. The typical treatment regimen for isolated urethritis is a single dose of ceftriaxone, 250 mg intramuscularly (IM), for gonorrhea, plus a single dose of azithromycin, 1 g orally, for Chlamydia; typical treatment of epididymitis is a single dose of ceftriaxone, 250 mg IM, plus doxycycline, 100 mg orally given twice a day for 10 days.

Epididymitis may also occur in prepubescent boys as a result of reflux of sterile urine into the epididymis; it often results from minor congenital genitourinary anomalies that need diagnostic evaluation. Treatment typically includes...

prophylactic antimicrobials to cover the common urinary pathogens.27

PRIAPISM
A urologist usually manages the treatment of priapism; however, in certain circumstances the emergency physician may have to initiate treatment of low-flow priapism. The classic teaching is that the initial treatment—oral (or subcutaneous) terbutaline—is the same regardless of the inciting etiology, although its utility is debated.28-30 It is thought that terbutaline, a β2-adrenergic agonist, increases venous outflow from the engorged corpora by way of relaxation of venous sinusoidal smooth muscle. Terbutaline is of unproved benefit; however, given its limited propensity for adverse effects, a trial is reasonable in selected circumstances while awaiting urology consultation.31

If terbutaline fails to work rapidly, the next step in the treatment of priapism is corporal blood aspiration with or without irrigation and injection of an α-adrenergic receptor agonist such as dilute phenylephrine. Phenylephrine should be diluted in normal saline to a concentration of 0.1 to 0.5 mg/mL and 1-mL injections made intermittently for upward of 1 hour. Lower concentrations in smaller volumes should be used in children and patients with severe cardiovascular disease.30

The goal of treatment for patients with sickle cell disease and priapism is reduction of red blood cell sickling, thereby reducing vascular sludging and vasoocclusion. Treatments in this setting include oxygen, intravenous hydration, and simple or exchange transfusions.

Regardless of the precipitating cause of priapism, surgical shunt procedures are used as a last resort in patients with low-flow priapism unresponsive to the aforementioned treatments.

PARAPHIMOSIS
Paraphimosis can frequently be managed in the ED without the need for emergency specialty consultation. Many methods for successful reduction of paraphimosis have been reported; however, the most commonly used initial maneuver involves manual compression of the distal glans penis to decrease edema, followed by reduction of the glans penis back through the proximal constricting band of foreskin.32

TESTICULAR TRAUMA
Patients with penetrating injury to the scrotum generally undergo exploration in the operating room. Patients with blunt testicular trauma and ultrasonographic evidence of significant testicular injury also generally undergo surgical exploration for débridement of devitalized tissue, treatment of an acute hematocele larger than 5 cm, or repair of the tunica albuginea.33 Documented testicular injury requires early repair to minimize the potential for infection, infarction, necrosis, abscess, infertility, atrophy, and testicular loss.

Nephrolithiasis
Carl R. Menckhoff

Stone impaction may occur anywhere along the path of the genitourinary tract. The resultant ureteral obstruction can shift hydrostatic pressure and cause blood flow to be redistributed to the opposite renal artery. The overall rate of glomerular filtration decreases as renal excretion becomes a task of the unaffected kidney. A transient increase in serum creatinine may follow this decrease in the glomerular filtration rate.

Although an initial rise in creatinine may quickly resolve, irreversible kidney damage can begin to occur after 7 days of complete obstruction.3,4 Prolonged obstruction impairs recoverable kidney function over time,4,5 but case reports show that some recovery may be possible for up to 150 days.5,6

Ureteral obstruction is primarily determined by calculus size. Most stones smaller than 5 mm in diameter will pass spontaneously (90%), whereas passage of stones larger than 8 mm is unlikely (5%). Table 112.1 compares ureteral stone size with the percent likelihood of spontaneous passage.

Stone impaction most commonly occurs at the ureterovesical junction, the narrowest part of the genitourinary tract. Other common areas of impaction include the ureteropelvic junction (where the renal pelvis narrows from 1 cm down to 3 mm).

and the pelvic brim (where the ureter arches anteriorly across the iliac vessels) (Fig. 112.1).

### CLINICAL PRESENTATION

#### HISTORY
Renal colic is classically manifested as a sudden onset of excruciating, intermittent flank pain that radiates to the groin. This swift onset of pain is often accompanied by a deeper flank ache, nausea, and vomiting. The severe, spasmodic pain of renal colic is thought to be caused by hyperperistalsis of smooth muscle from the calices to the ureter. The dull, deep, aching pain reflects ureteral obstruction and distention of the renal capsule.

The location of the ureteral calculus determines the symptoms, as outlined in Table 112.3.

#### PHYSICAL EXAMINATION
Patients with renal colic typically appear uncomfortable and are commonly described as “writhing” on the gurney. Findings on the abdominal examination are generally unremarkable, although thin patients with distal ureteral stones and obstruction may exhibit some tenderness. Tenderness at the costovertebral angle can develop as a result of worsening hydronephrosis; this sign is mild or absent early in the course of the disease. Abnormal findings on physical examination should raise suspicion for alternative diagnoses, as reviewed in Table 112.4.

### DIFFERENTIAL DIAGNOSIS

Many disease processes can mimic symptomatic nephrolithiasis. Abdominal aortic aneurysm, aortic dissection, renal artery
dissection, and renal infarction are the most lethal conditions that may manifest similar to renal colic. In one study, abdominal aortic aneurysms were initially misdiagnosed as kidney stones in approximately 20% of patients older than 60 years. Box 112.2 lists the differential diagnosis for renal colic.

### Diagnostic Testing

#### Laboratory Tests

**Urinalysis**

A bedside urine dipstick test or urinalysis should be performed in all patients with suspected renal colic to evaluate for hematuria and infection. Urine culture should be ordered if leukocytes, nitrites, or bacteria are identified.

Hematuria is a common but inconsistent finding in patients with ureteral stones. The amount of gross or microscopic hematuria does not correlate with stone impaction or the degree of obstruction; rather, hematuria results from direct ureteral trauma caused by the passing stone. Hematuria is absent in 15% of patients with ureteral stones.

Alkaline urine (pH > 7.6) may indicate infection with a urea-splitting organism, a common finding in patients with struvite stones. Urine pH lower than 5.0 suggests the presence of a uric acid stone.

Uric acid or oxalate crystals may be detectable in urine in a variety of conditions; this finding does not imply the presence of nephrolithiasis, however, and should be interpreted with caution.

**Urine Pregnancy Test**

Urine human chorionic gonadotropin levels should be checked in female patients of childbearing age. Although pregnant patients may have renal colic, a newly positive result should raise suspicion for ectopic pregnancy in the differential diagnosis.

**Blood Tests**

Blood urea nitrogen and creatinine can be measured if the symptoms have been prolonged or renal impairment is a concern, but these tests are not routinely indicated.

</tbody>
</table>

Fig. 112.3 Noncontrast renal protocol computed tomography scan showing a stone at the left ureteropelvic junction (arrow).

If a complete blood count is obtained, increased leukocytosis should be interpreted with caution because it can indicate either pain-induced demargination or infection.

A baseline hemoglobin level should be considered in the evaluation of patients with persistent gross hematuria or hemodynamic compromise.

**IMAGING**

ED imaging (Table 112.5) is used to confirm the diagnosis of nephrolithiasis, evaluate stone size, identify obstruction, and exclude alternative diagnoses. Patients with decreased renal reserve (solitary kidney, uncontrolled diabetes mellitus, uncontrolled hypertension), concurrent infection, first occurrence of stone disease, advanced age, and prolonged or unremitting symptoms should undergo imaging during their initial evaluation. Indications for emergency imaging in cases of suspected renal colic are summarized in Table 112.6.

**Helical Computed Tomography**

Noncontrast helical computed tomography (CT) of the abdomen and pelvis is the preferred imaging modality for the evaluation of patients with suspected nephrolithiasis. CT imaging for renal stones can be performed without contrast material, demonstrates both high sensitivity (94% to 100%) and specificity (96% to 100%),11-15 and allows alternative diagnoses to be simultaneously identified.15,16 Sagittal images are obtained at 5-mm intervals from the top of the kidney to the bottom of the bladder (Figs. 112.2 and 112.3).

**Intravenous Pyelography**

Intravenous pyelography (Fig. 112.4) has a sensitivity of 52% to 85% and specificity of 97% to 100% for detection of ureteral calculi.11,17,18 It provides a visual interpretation of renal function, as well as genitourinary anatomy. The earliest sign of ureteral obstruction on an intravenous pyelogram
is a delayed nephrogram; other abnormal findings include a “standing column” (the entire ureter seen on one image; Fig. 112.5), hydroureter, hydronephrosis, contrast cutoff at the point of impaction, and extravasation of contrast material. The use of intravenous pyelography is limited by the need for contrast material, decreased sensitivity in comparison with helical CT, and the length of time required to obtain multiple delayed images.

Fig. 112.6 Renal ultrasound showing moderate hydronephrosis.

**Sonography**

Ultrasongraphy is a useful modality for identifying hydronephrosis caused by ureteral obstruction (Fig. 112.6). Advantages include its ease of use and rapid acquisition of diagnostic images at the bedside without the need for contrast agents or radiation. It is the imaging technique of choice for the evaluation of suspected renal colic in pregnancy. Ultrasonography is limited by false-negative results, which occur in patients with small calculi that do not cause significant obstruction or hydronephrosis. The sensitivity and specificity of ultrasonography for the diagnosis of urologic stone disease is 66% to 93% and 83% to 100%, respectively.18-20
setting of ureteral obstruction, thereby improving symptoms through a decrease in urine production and ureteric pressure. Ketorolac (Toradol) (30 mg intravenously or 60 mg intramuscularly) has efficacy equivalent to the oral administration of 800 mg of ibuprofen, although the latter may be less well tolerated in patients with concomitant nausea.

Some urologists debate the routine use of NSAIDs for the treatment of nephrolithiasis because these medications may promote bleeding after the placement of a ureteral stent. Data to support such observations are inconclusive.

Opiates

Intravenous narcotics provide adequate relief of symptoms for most patients with renal colic. Opiates have similar analgesic effects at equivalent dosing. Although meperidine (Demerol) demonstrates smooth muscle relaxation when tested in vitro, this spasmolytic effect does not appear to improve its clinical utility in therapy for renal colic. Given the potential for drug interactions with meperidine, preferred opiates for ED use include hydromorphone (0.015 mg/kg) and morphine (0.1 mg/kg starting dose).

</tr>
</tbody>
</table>

Multiple studies have shown that both NSAIDs and opiates are effective and appropriate treatments of renal colic. One metaanalysis of 19 studies showed that NSAIDs and opiates are equally effective in the acute management of renal colic symptoms. Many experts recommend the use of NSAIDs followed by opiates for continued pain.

**MANAGEMENT OF OTHER SYMPTOMS**

Tamsulosin (Flomax), an α-adrenergic blocker, reduces ureteral spasm. Early studies suggested that oral tamsulosin (0.4 mg/day) helps promote ureteral passage of juxtavesical stones. There continue to be more studies supporting such treatment, as well as studies now indicating that tamsulosin may be useful for more proximal stones as well. Calcium
channel blockers have been studied for their smooth muscle relaxant effects, and some studies suggest that they also promote stone expulsion. Antiemetics should be administered to patients experiencing concomitant nausea or vomiting. Intravenous crystalloid administration was once thought to promote stone migration by stimulating ureteral peristalsis; however, no supporting evidence has shown that hydration consistently improves symptoms by this mechanism.

**RED FLAGS**

Patients older than 60 years: Consider a vascular cause of their pain.

Signs of infection: Exclude concurrent obstruction.

Large calculi: 5-mm stones have a 50% chance of passing; stones larger than 8 mm have a 5% chance of passing.

**DISPOSITION**

Patients with uncomplicated renal colic whose symptoms are easily controlled should be discharged with analgesics, a urine strainer, antiemetics, and follow-up within 7 days. Stones captured by urine straining should be brought to the urologist for pathologic evaluation. Return precautions include uncontrolled pain, protracted vomiting, and fever (Fig. 112.8).

![Guideline algorithm for the evaluation, treatment, and disposition of patients with presumed renal colic. CT, Computed tomography; IV, intravenously; US, ultrasonography.](image-url)
A urologist should be consulted if patients have uncontrol-
lable pain or evidence of infection. The presence of white
blood cells in urine may indicate an infection and, in the pres-
ence of obstruction, warrants urology consultation for urgent
stone removal or stenting.

Some patients will have a few white blood cells in their
urine (e.g., <10) but no clinical signs of infection. These
patients will be otherwise asymptomatic following medica-
tion for pain (i.e., afebrile). In the absence of concomitant
obstruction, urgent stone removal in such cases is not routine.
Patients with coexisting, complicating diseases may be treated
with antibiotics and observed in the hospital. Patients without
underlying disease may be treated with antibiotics as an out-
patient and monitored carefully. A urine culture should be
performed for patients with white blood cells in their urine.

**Box 112.3** summarizes common indications for admission
or urology consultation.

Hematuria

M. Kit Delgado and Eva M. Delgado

KEY POINTS

- Hematuria can be a transient and incidental finding, or it can be caused by underlying and otherwise silent life-threatening disease.
- Infection is the most common cause of symptomatic hematuria in all age groups. Crystalluria and glomerulonephritis are more common in children; malignancy and nephrolithiasis are more common in adults.
- Patients with microscopic hematuria should have urinalysis repeated with their primary care provider about 1 week after discharge from the emergency department.
- All patients with gross hematuria warrant careful evaluation to ensure adequate urinary drainage. Those with difficulty passing clots, evidence of retention, or poor mobility should have a three-way Foley catheter placed in the emergency department.
- Although hematuria alone is rarely grounds for admission, emergency associated disease processes should be considered and excluded. Such processes include urosepsis, obstructing ureteral stone, renal parenchymal disease, coagulopathy, symptomatic anemia, intraabdominal injury in the setting of trauma, renal vein thrombosis, and aortic abdominal aneurysm.

SCOPE AND DEFINITIONS

Hematuria is the abnormal excretion of red blood cells (RBCs) in urine. Regardless of whether it is a chief complaint or an unexpected discovery, the emergency provider must be able to distinguish between serious and nonserious causes of hematuria. Evaluation begins with classification into four broad categories: (1) gross (macroscopic); (2) microscopic, symptomatic; (3) microscopic, asymptomatic; and (4) pigmenturia (pseudohematuria).

Gross (macroscopic) hematuria, visualized as red-colored urine, is disconcerting to most patients, but it does not always imply significant blood loss: as little as 1 mL of blood may turn 1 L of urine red. Dysuria is common in patients with gross hematuria, and urinary retention may develop if high-volume bleeding leads to clots that obstruct urethral outflow. Microscopic hematuria refers to the detection of more than three RBCs per high-power field (HPF) in a spun sample of urine sediment not visible to the naked eye. Screening of asymptomatic individuals suggests that up to 10% of adults and 6% of children may have some degree of microscopic hematuria at any given time. Typically an incidental and transient discovery, it can be associated with dysuria or pain. Because microscopic hematuria may be the only clue to previously undiagnosed structural, neoplastic, or inflammatory conditions, follow-up is essential.

Pigmenturia (pseudohematuria) refers to urine that appears red or dark without RBCs detected by urine microscopy. A urine dipstick may register a positive test result for blood if hemoglobin, myoglobin, or bilirubin is present in the urine, as in the case of hemolysis, rhabdomyolysis, or jaundice. Pigmented urine with a negative dipstick test result may be caused by certain foods or medications (Table 113.1).

PATHOPHYSIOLOGY

Hematuria results from the admixture of blood and urine as a result of infection, inflammation, or injury at any point along the genitourinary tract. Causes of hematuria can be divided into glomerular and nonglomerular (see Table 113.1). Glomerular causes, such as glomerulonephritis, are more common in children than in adults and are frequently associated with systemic medical illness. Nonglomerular causes of hematuria can be further classified as renal (e.g., papillary necrosis), extrarenal (e.g., bladder cancer), traumatic (e.g., renal contusion), coagulopathy related (e.g., patient taking warfarin), and factitious (e.g., Munchausen syndrome).

Minor trauma caused by high-impact exercise, such as long-distance running, can produce transient microscopic hematuria. Persistent or high-volume bleeding is generally pathologic and mandates further evaluation.

CLINICAL PRESENTATION

The signs and symptoms in patients with hematuria vary greatly, depending on the underlying cause and degree of hematuria. Incidental discovery of microscopic hematuria is generally noted when providers have urinalysis performed for another reason (e.g., suspected urinary tract infection). Increasing concentrations of blood in urine and persistent

Hematuria in the Pediatric Patient

| Recent illness (pharyngitis, impetigo, viral illness) | Postinfectious glomerulonephritis |
| Abdominal pain | UTI, hypercalciuria, stone, HSP |
| Concurrent illness | IgA nephropathy |
| Arthralgias | HSP, SLE |
| Diarrhea (+ bloody) | HUS |
| Hearing loss | Alport syndrome |
| Family history of hematuria or kidney disease | Polycystic kidney disease, hypercalciuria, Benign familial hematuria, thin basement disease, Alport syndrome |
| Rash (purpura, petechiae) | Bleeding dyscrasia, abuse, HSP, SLE, HUS |
| Edema | Glomerulonephritis, nephrotic syndrome |
| Abdominal mass | Wilms tumor, hydronephrosis, polycystic kidney disease |
| Conjunctivitis, pharyngitis | Adenovirus (hemorrhagic cystitis) |
| Meatal erythema or stenosis | Masturbation, infection, trauma |

Continued
bleeding will result in dysuria, clot formation, and eventually bladder outlet obstruction. If left untreated, urinary retention, suprapubic pain, flank pain, and renal failure may ensue.

**DIFFERENTIAL DIAGNOSIS**

Hematuria may be a sign of a large number of diseases (see Table 113.1).\(^1\),\(^9\) Infection at any location in the genitourinary tract can cause hematuria and is the most common cause of hematuria in both adults and children.

Nephrolithiasis is the second most common cause of hematuria in adults (see Chapter 112). Microscopic hematuria is a common finding in patients with suspected ureteral colic and is caused by abrasion of mucosal tissue by the stone; however, hematuria may be absent in patients with complete ureteral obstruction.\(^6\) Thus, exclusion of the diagnosis of a ureteral stone should not be based solely on negative findings on urinalysis. Although nephrolithiasis is not as common in children, it must remain part of the differential diagnosis. Hypercalciuria is often associated with recurrent asymptomatic microscopic hematuria, and affected children may face higher risk than their peers for the development of nephrolithiasis.\(^7\)

Glomerulonephritis, responsible for 10% of cases of gross pediatric hematuria, is usually accompanied by systemic symptoms such as hypertension.\(^8\) Systemic lupus erythematosus and other chronic inflammatory disorders can also cause hematuria by similar mechanisms.\(^2\),\(^5\),\(^6\),\(^8\)

The family history may provide a clue to glomerulonephritis and other disorders associated with hematuria that are due to rare genetic causes (see Table 113.1).\(^2\),\(^5\),\(^6\),\(^8\)

**DIAGNOSTIC TESTING**

The point-of-care urine dipstick test can detect the equivalent of 1 to 2 RBCs/HPF. False-positive results can occur with
myoglobinuria and hemoglobinuria.\textsuperscript{5,6} If a urine dipstick test is positive for the detection of blood, standard urinalysis should be performed. Urinalysis is highly sensitive and specific; however, it is more expensive and time intensive than the urine dipstick test. Urinalysis quantifies the amount of blood present and can differentiate the presence of myoglobin or hemoglobin.\textsuperscript{2} Thus in the appropriate context, patients with a urine dipstick positive for blood and negative findings on urinalysis should be evaluated for rhabdomyolysis, hemolysis, or hyperbilirubinemia.

The presence of casts, dysmorphic RBCs, and proteinuria is associated with glomerular causes of hematuria (Table 113.2).

Incidental microscopic hematuria without associated symptoms or hemodynamic instability mandates confirmation of normal blood pressure in pediatric patients as a screen for glomerulonephritis, obstructive uropathy, or other systemic disease.\textsuperscript{2,8} Normotensive patients require no further testing in the emergency department (ED), but all patients will need follow-up evaluation as an outpatient.\textsuperscript{2,5,6,8}

Urinal culture should be considered in the setting of suspected infection, especially in pediatric patients or those with indwelling Foley catheters. Urine calcium and creatinine determination is useful in a child with hematuria who does not have a urinary tract infection or a glomerular cause to confirm the diagnosis of hypercalciuria (urine calcium-creatinine ratio > 0.2).\textsuperscript{2,7,8} Urine cytology for malignancy has poor sensitivity in the ED setting and should not be ordered as part of the ED evaluation.\textsuperscript{1}

In patients with gross hematuria or symptomatic microscopic hematuria, blood should be sent for a complete blood cell count and renal function testing (blood urea nitrogen, creatinine). A coagulation panel should be ordered for patients who are taking anticoagulants or have a suspected or known coagulopathy.\textsuperscript{7} Patients with unstable vital signs, heavy bleeding, and symptomatic anemia should have blood typed and screened for a potential transfusion.

Although hematuria associated with flank pain may suggest a ureteral stone, a rupturing abdominal aortic aneurysm or renal vein thrombosis should be considered in the differential diagnosis (see Table 113.1).\textsuperscript{6} For this reason, imaging can be used to exclude these emergency diagnoses when clinically indicated (Fig. 113.1).\textsuperscript{1,2} Ultrasonography is useful for the evaluation of microscopic hematuria in children and as a screen for obstruction, hydronephrosis, and abdominal aortic aneurysm.\textsuperscript{1,2,6} It is less expensive than computed tomography (CT) and is safer because of lack of radiation and intravenous contrast agents. Non–contrast-enhanced CT may be used to indentify the size and location of renal stones. Contrast-enhanced CT is more sensitive than ultrasound for the detection of small renal masses. Contrast-enhanced CT is necessary to elucidate the integrity of intraabdominal and retroperitoneal structures in the setting of significant trauma associated with hematuria.\textsuperscript{5,6,8,10-12}

In pediatric victims of significant blunt thoracoabdominal trauma, microscopic hematuria consisting of more than 5 RBCs/HPF indicates the need for further evaluation with abdominal and pelvic CT.\textsuperscript{10} For pediatric trauma patients who are not toilet-trained, bag urine collection may be preferred over catheterization as a screen for hematuria because the trauma from catheterization can lead to false-positive urine specimens.

In adults with blunt trauma, a higher cutoff (>50 RBCs/HPF) for microscopic hematuria is associated with increased risk for intraabdominal injury worthwhile of abdominal and pelvic CT.\textsuperscript{11} As a screen for bladder injury, gross hematuria has greater sensitivity and specificity than microscopic hematuria does.\textsuperscript{12}

### TREATMENT AND DISPOSITION

Treatment varies depending on the underlying diagnosis and degree of hematuria (see Fig. 113.2). Intravenous fluids, analgesics, and antiemetics may be needed in patients with gross hematuria.

Patients with gross hematuria who are able to void should be asked about the presence of clots in their urinary flow and the ease with which they are passed. Foley catheterization may
Classify type of hematuria; history and physical:
- See Fig. 113.1
- Measure blood pressure in children
- Blood work as indicated

Gross hematuria

Microscopic hematuria, symptomatic
- Eumorphic RBCs
- No red cell casts
- No proteinuria
- Resuscitate as needed

Microscopic hematuria, asymptomatic
- Dysmorphic RBCs
- Red cell casts
- Proteinuria
- General practitioner/primary care follow-up

Pseudohematuria (pigmenturia)

Indications for three-way Foley catheter irrigation:
- Passing clots with difficulty
- Evidence of urinary retention

Evaluate for glomerular causes; consult/referral to nephrology (Ch. 114)

Evaluate for nonglomerular causes

*US positive for AAA or hydronephrosis warrants further evaluation by CT

Indications for urology consultation and admission for gross hematuria:
- Unstable vital signs, symptomatic anemia
- Heavy hematuria with clots
- Urinary retention/renal failure
- Coagulopathy
- Severe comorbidity
- Social restrictions
- Uncontrolled pain or vomiting

Safe for discharge
1. Emergency conditions considered and excluded from differential diagnosis:
- Urosepsis
- Obstructing ureteral stone with UTI and/or renal insufficiency
- Conditions progressing toward renal failure
- Coagulopathy with multiple sites of bleeding
- Traumatic injury
- Renal vein thrombosis or embolic phenomena
- Ruptured or expanding AAA
2. Referral to general practitioner, urology, or nephrology follow-up as indicated

Fig. 113.2 Management algorithm for hematuria. AAA, Abdominal aortic aneurysm; CT, computed tomography; RBCs, red blood cells; US, ultrasound; UTI, urinary tract infection.
be avoided in stable, sensible, and mobile patients who are able to void easily and who have a few small clots that pass with ease. If clot retention or significant dysuria is present, the treatment of choice is insertion of a three-way Foley catheter to facilitate irrigation of the bladder to dislodge clots and allow bladder decompression. If saline should be irrigated continuously through the third port until the urine turns pink to clear and is free of clots. In the setting of trauma, urethral injury should be excluded before catheter placement (see Chapter 82). Stable patients with improved symptoms may be discharged with a leg bag and instructions for urology follow-up in 3 to 5 days.

Consultation with a nephrologist may be helpful in cases of suspected glomerular disease or obstructive uropathy in a child. Urology consultation should be obtained for patients with malignancies and for patients with high-volume, noninfectious gross hematuria. Hematuria alone is rarely an indication for admission, except as noted in Figure 113.2.1,6

The vast majority of patients with hematuria are discharged with further care as an outpatient. Incidental cases require repeated urinalysis in 1 week.1,4,6 Patients treated for gross hematuria should be instructed to drink plenty of fluids and return if they have an inability to void, fever, pain, worsening dysuria, and gross hematuria that fails to clear.

Renal Failure
William J. Brady and Amita Sudhir

Management of renal failure in the emergency department should be aimed at identifying and treating life-threatening abnormalities associated with the disorder, identifying reversible causes of renal failure, and preventing further injury to the kidneys.

Acute pulmonary edema and hyperkalemia are potentially life-threatening complications of renal failure.

Severe hyperkalemia should be suspected as the cause of cardiac arrest in patients with a possible history of renal failure.

An electrocardiogram should be obtained for all patients with renal failure on arrival at the emergency department to screen for hyperkalemia.

DEFINITIONS

Renal failure can be the result of a wide variety of conditions that cause injury to the kidneys. Recently, there has been a change in terminology with respect to kidney disease: the entities previously known as acute renal failure and chronic renal failure are now known as acute kidney injury and chronic kidney disease, respectively.

The Acute Kidney Injury Network (AKIN) provides the following criteria for the diagnosis of acute kidney injury: an abrupt (within 48 hours) reduction in kidney function currently defined as an absolute increase in serum creatinine of 0.3 mg/dL or greater (≥26.4 µmol/L), a 50% or greater increase in serum creatinine of 1.5-fold higher than baseline, or a reduction in urine output (documented oliguria of less than 0.5 mL/kg/hr for more than 6 hours).1

Two classification systems describe the stage of renal disease. The first, created by the Acute Dialysis Quality Initiative, is the RIFLE (risk, injury, failure, loss, and end-stage kidney disease) classification system, which bases severity on the degree of change in serum creatinine or urine output from a baseline measurement (Table 114.1).2 The second was created by AKIN. Although it is modeled on the RIFLE classification, it does not require the physician to know the patient’s baseline creatinine level. Its ease of use in the emergency department (ED) is improved by the fact that it does not use the glomerular filtration rate (GFR) as one of the criteria for staging kidney injury. The AKIN criteria are to be applied after adequate fluid resuscitation has taken place, and the authors of the criteria also recommend excluding easily reversible causes of kidney failure, such as urinary outflow obstruction (Table 114.2).1

The National Kidney Foundation’s clinical practice guidelines define patients with chronic kidney disease as meeting one of the following criteria: (1) kidney damage for 3 or more months, defined as structural or functional abnormalities of the kidney, with or without an increased GFR, and demonstrated by either pathologic abnormalities or markers of kidney damage, including abnormalities in blood or urine or abnormal findings on imaging tests; or (2) a GFR lower than 60 mL/min/1.73 m² for 3 or more months, with or without kidney damage.3 The complicated definition of chronic kidney disease plus the need to monitor kidney function over an extended period means that it is unlikely that chronic kidney disease will be convincingly diagnosed in the ED. However, it is useful for the emergency physician (EP) to understand what it means when a patient has preexisting chronic kidney disease, as well as to be vigilant for suspected, but previously undiagnosed chronic kidney disease in a patient with the appropriate signs and symptoms.

EPIDEMIOLOGY

The prevalence and incidence of kidney failure in the United States are rising. The prevalence of chronic kidney disease is estimated to be greater than 10%.4 The annual incidence of acute kidney injury is 100 per 1 million population. The incidence of acute kidney injury in the community varies widely depending on the population, but hospital-acquired rates can be quite high, with as many as 30% of critical care patients in some studies developing acute kidney injury.5

PATHOPHYSIOLOGY

The kidneys are located in the retroperitoneal space and are composed of three basic structures: vasculature, parenchyma,
The kidney is responsible for maintaining the volume and ionic composition of body fluids, excreting metabolic waste products such as urea, and eliminating exogenous drugs, hormones, and toxins. The kidneys also serve as a major endocrine organ through the production of renin, erythropoietin, 1,25-dihydroxycholecalciferol, prostaglandins, and kinins. Metabolic functions of the kidney include catabolism of small-molecular-weight proteins and anabolic roles in ammoniagenesis and gluconeogenesis.

In a person weighing 70 kg, the kidney forms approximately 180 L of glomerular filtrate each day. Cardiac output in combination with effective intravascular volume generates hydraulic pressure that drives fluid from the capillaries into the urinary space, which represents the main mechanism of urine formation. The final urinary filtrate is determined by a complex interaction between hydraulic and oncotic pressure, molecular size and charge, absorption, reabsorption, and secretion under hormonal control.

Renal failure can be the result of dysfunction in any part of this system. It is helpful to understand the pathophysiology of renal disease as a set of three etiologic categories: prerenal, intrinsic renal, and postrenal causes.

1. Prerenal failure results from the kidneys not receiving enough blood via a cause external to the kidneys themselves; it results in a reduced GFR, buildup of toxic waste products, and damage to the kidneys persisting after the underlying cause has been corrected. Causes of prerenal failure include hypovolemia, decreased cardiac output, and septic shock.
2. Renal failure may be caused by diseases intrinsic to the kidneys, including genetic syndromes such as polycystic kidney disease, infections, vascular diseases, and toxins or drugs.
3. Postrenal failure may result from obstruction to urinary flow external to the kidneys themselves. The obstruction causes increased fluid pressure within the nephron, which ultimately leads to loss of function. Urteral stones, prostatic hypertrophy, tumors, and anticholinergic medications are some possible causes of postrenal kidney failure.

and the collecting system. The kidneys receive about a quarter of the body’s total cardiac output through the renal arterial system and an extensive network of arteries, arterioles, and capillaries that eventually drain into the renal vein. The renal parenchyma is composed of the medulla and cortex, which houses the functional unit of the kidney, the nephron. A single nephron consists of a glomerulus, proximal tubule, thin limbs of Henle, and a distal tubule. The connecting tubule joins the nephron to the collecting system, including the renal pelvis, minor and major calyces, and the ureter, bladder, and urethra (Fig. 114.1).

The kidney is responsible for maintaining the volume and ionic composition of body fluids, excreting metabolic waste...
Renal failure can be divided into two categories: primary disturbances and secondary disturbances. Primary disturbances reflect a direct failure of the kidneys to perform critical functions, such as failure to excrete sodium (leading to volume overload) or a decrease in erythropoietin production (leading to anemia). Secondary disturbances result from an accumulation of metabolic products in other organ systems, as when hyperphosphatemia causes hyperparathyroidism or when nitrogenous waste products promote platelet dysfunction. The combination of primary and secondary disturbances disrupts the homeostatic balance of almost every organ system.

**PRIMARY DISTURBANCES**

When the kidney can no longer perform excretory functions, the result is volume overload, hyperkalemia, and hyperphosphatemia. As renal endocrine function declines, hypocalcemia and anemia develop. Renal failure can cause an increased circulating concentration of insulin and lower insulin requirements in diabetics. Loss of ammoniagenesis and the ability to excrete phosphate impairs clearance of the metabolic acid load by the kidneys and may lead to acidosis. Adverse drug reactions at normal dosages can occur when drugs that are metabolized or excreted by the kidneys are administered.

**SECONDARY DISTURBANCES**

Accumulation of nitrogenous waste products, generically referred to as uremia, is a characteristic of not only renal excretory failure but also a host of metabolic and endocrine disease states. Derangements in protein, carbohydrate, and lipid metabolism will ensue and are associated with anemia, malnutrition, and metabolic bone disease. Loss of renal catabolism and an increase in endocrine secretion affect many hormones, including insulin, glucagon, luteinizing hormone, and prolactin. A normal platelet count may be maintained, although platelet function and bleeding time will probably become abnormal. Poorly understood immune system interactions can lead to immunosuppression, overwhelming infection, septic shock, and death.

**PRESENTING SIGNS AND SYMPTOMS**

Manifestations may vary greatly depending on the cause of the renal failure, but patients may describe a history of volume overload or decreased urine output. They may also have one or many of a long list of end-organ effects (Table 114.3). Renal failure is not a diagnosis that is necessarily obvious on initial encounter and is often made only after screening laboratory data are obtained.

Once the laboratory diagnosis of renal failure is made, the EP should go back through the patient’s history to look for signs and symptoms and findings on physical examination that suggest the cause of the renal failure, as well as signs of any complications that must be dealt with urgently. Pulmonary edema, cardiac arrhythmias, and altered mental status are particularly concerning findings.

**Differential Diagnosis and Medical Decision Making**

Although the classic teaching has been that fractional excretion of sodium and urea be used to determine the source of the renal dysfunction—prerenal, intrinsic renal, or postrenal—these calculated values are often unreliable indicators of the cause of renal failure, especially in the setting of diuretic use and underlying chronic renal disease. Their diagnostic value or usefulness in guiding therapy in the ED is questionable. Physical examination findings and the clinical history are more useful in determining the cause of the renal failure. Fractional excretion of sodium and urea can be used to support a conclusion or help eliminate alternative diagnoses.

Once a diagnosis of renal failure is made through creatinine screening or the presence oliguria or anuria (Box 114.1), a differential diagnosis of underlying conditions and complications should be generated by considering potential diseases of the vasculature, parenchyma, and collecting system, as well as conditions external to the kidneys that lead to decreased blood flow or obstruction to the flow of urine.

**Intrinsic Renal Failure: Vascular Causes**

Vascular diseases of the kidney are manifested differently according to the size of the artery involved (Box 114.2). Sudden back or flank pain suggests large vessel aneurysm, dissection, embolism, or trauma. Poorly controlled hypertension and chronic renal insufficiency suggest renal artery stenosis. Systemic manifestations such as rash and fever suggest vasculitis in the smaller vessels of the kidney.

**Box 114.1 Diagnostic Criteria for Acute Kidney Injury**

An abrupt (within 48 hours) reduction in kidney function as defined by the following:

- An absolute increase in serum creatinine of 0.3 mg/dL or greater
- A 50% or greater increase in serum creatinine (1.5-fold higher than baseline)
- A reduction in urine output (documented oliguria of less than 0.5 mL/kg/hr for more than 6 hours)

**Box 114.2 Causes of Renal Failure Secondary to Vessel Injury**

Small and Medium Vessel
- Scleroderma
- Malignant hypertension
- Hemolytic-uremic syndrome
- Thrombotic thrombocytopenic purpura
- Sickle cell nephropathy
- Preeclampsia
- Trauma

Large Vessel
- Renal artery thrombosis or stenosis
- Renal vein thrombosis
- Atheroembolic disease
- Aortic dissection
- Angiography

**Intrinsic Renal Failure: Parenchymal Causes**

The working unit of the kidney is the nephron, which is composed of a variety of cell types that are susceptible to many disease processes (Box 114.3). The medical history is invaluable in identifying the root cause within this category of kidney failure.

**Obstructive Renal Failure**

The collecting system of the kidneys is composed of the calyces, renal pelvis, ureter, bladder, and urethra—obstruction may occur at any level (Box 114.4). Obstruction to urinary flow is generally a reversible cause of renal failure. Alert patients may have symptoms of urinary retention or nephrolithiasis that are dramatic and obvious. Occult, potentially reversible renal obstruction should be considered in patients with altered mental status and acute renal failure.

**Urinary Formation Problems Resulting in Renal Failure**

Also known as prerenal kidney failure, problems with urine formation should be suspected in patients with volume depletion, decreased cardiac output, or third spacing of fluid as a result of any cause. The various causes of prerenal kidney failure are summarized in Box 114.5.

**Treatment**

**Prehospital Management**

If the patient’s history suggests a possible diagnosis of renal failure, the prehospital provider should consider hyperkalemia...
as a cause of any electrocardiographic (ECG) changes and treat the patient accordingly. Fluid should be administered judiciously to patients with renal failure, with awareness of the patient’s impaired ability to excrete fluid and the possibility of subsequent volume overload.

**HOSPITAL MANAGEMENT**
ED management of patients with renal failure should be aimed at (1) identifying any easily reversible causes of renal failure, (2) preventing and treating life-threatening abnormalities caused by renal failure, and (3) supportive therapy to prevent further injury to the kidneys. Patients receiving renal replacement therapy (dialysis of any kind) and those with known renal abnormalities who exhibit worsening of their renal function (“acute on chronic failure”) should be treated the same as patients without a history of renal insufficiency.

**Treating Reversible Causes of Renal Failure**
Hypovolemic patients should be given appropriate fluid resuscitation while taking precautions to avoid volume overload. Appropriate fluid resuscitation may result in return of renal function.

Patients with known or suspected urinary outflow obstruction in or distal to the bladder should be treated with a Foley catheter.

In cases of parenchymal injury, any obvious toxic exposures (drugs, antibiotics, toxins) should be stopped, proper hydration should be provided, and infections or severe shock states should be treated.

The use of specific antidotes and pharmacologic treatments (e.g., bicarbonate and mannitol for patients with rhabdomyolysis) and the use of diuretics to improve urine flow are controversial; consultation should be obtained before initiating any therapy (beyond fluid replacement) aimed at maintaining adequate urine output.6

Treatment of vascular compromise in large vessels (embolization, thrombosis, dissection) should focus on return of normal blood flow. Consultation with urology, vascular surgery, or interventional radiology may be required. Treatment of small vessel disease should be focused on therapy for the underlying illness.

**Other Treatment Considerations**
Particular care should also be taken with the administration of renally cleared drugs, such as morphine or insulin, which could be harmful or even fatal if blood concentrations rise.

Intravenously administered contrast material may cause additional kidney injury. If patients are receiving renal replacement therapy, contrast material may be administered in consultation with a nephrologist if dialysis is to take place in a timely manner (Box 114.6).

**Life-Threatening Complications of Renal Failure**

**Volume Overload**
Extracellular fluid volume is determined by the balance between sodium and water. Renal failure may promote sodium retention or result in failure to excrete...
excessive sodium intake, thereby leading to a positive sodium balance and extracellular fluid volume expansion. The most concerning clinical manifestation of volume overload is pulmonary edema with respiratory distress. The presence or lack of previous renal replacement therapy should not alter the management of acute pulmonary edema. Volume overload remains one of the most common reasons for emergency dialysis—dialysis should be considered as early as possible in patients with renal failure and severe pulmonary edema.

Hyperkalemia One of the most lethal complications of renal failure is hyperkalemia. Any patient suspected of having renal failure or hyperkalemia should undergo a screening ECG study on arrival at the ED. Peaked T waves are pathognomonic for hyperkalemia. Later changes include bradycardia, widening of the QRS complex, and degeneration into a sine wave pattern. These changes can all occur without preceding peaked T waves. Patients with ECG changes consistent with hyperkalemia should receive treatment immediately—do not wait for serum confirmation. However, because normal ECG findings do not exclude hyperkalemia, serum confirmation should be made when suspicion for hyperkalemia remains high, as it should in all patients with known or suspected renal failure. In patients with previous chronic kidney disease, significant dietary changes, new medications, and noncompliance with dialysis can precipitate hyperkalemia.

All patients with known renal failure who are initially seen in cardiac arrest should be treated for the hyperkalemia along with the usual resuscitative measures. The extremities and upper part of the chest should be checked for dialysis access devices when patients are in cardiac arrest, and their presence should be assumed to be diagnostic of preexisting renal failure.

Other Electrolyte and Acid-Base Disturbances Additional metabolic derangements seen in cases of renal failure include hypermagnesemia, hypernatremia, hyponatremia, hypercalcemia, hypocalcemia, hyperglycemia, hypoglycemia, and metabolic acidosis (refer to specific treatment strategies in corresponding chapters of this text). In many instances, severe electrolyte disturbances mandate urgent dialysis.

Chest Pain The leading cause of death in patients with renal failure is acute coronary syndrome. Preceding illnesses (diabetes, hypertension) compounded with complications of renal failure (dyslipidemia, chronic volume overload, hyperphosphatemia, anemia, hyperparathyroidism) present a host of risk factors for the development of coronary artery disease.

---

**BOX 114.6 Management Considerations for Patients with Renal Failure**

**Intravenous Access**
Avoid the side of grafts and fistulas. In life-threatening emergencies, grafts and fistulas may be accessed.

**External Blood Pressure Measurements**
Avoid the side of grafts and fistulas.

**Volume and Electrolyte Replacement**
Careful titration of fluid administration is necessary to avoid volume overload and pulmonary edema.
Avoid aggressive electrolyte replacement.

**Medications**
Adjust dosages according to creatinine clearance.
Avoid nephrotoxic antibiotics.
Anticoagulants may need to be adjusted (low-molecular-weight heparin).

**Radiographic Contrast Agents**
If no renal function remains, contrast dye should be tolerated.
Avoid intravenous contrast agents in patients with remaining renal function.

**Procedures**
Increased risk for bleeding is possible.

---

**Chapter 114: Renal Failure**

**Volume Overload and Pulmonary Edema**
Assess the airway and ventilation
- Intubation, CPAP, or BiPAP as necessary

Provide supplemental O₂
- 100% non-rebreather mask if the above measures are not used

Position the patient upright
Apply a cardiac monitor
- Look for contributing dysrhythmias

Obtain intravenous access
Obtain an ECG
- Screen for hyperkalemic changes

Venodilating agents
- Nitroglycerin: SL or intravenous drip
- Nitroprusside
- ACEI if hypertensive

Diuretics
Inotropes or vasopressors as necessary
Urgent consultation for dialysis

ACEI: Angiotensin-converting enzyme inhibitor; BiPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure; ECG, electrocardiogram; SL, sublingual.

---

**Treatment of Hyperkalemia**
Stabilize the myocardium against the effects of potassium
- Calcium gluconate or calcium chloride, 1 g IV

Induce an intracellular shift of potassium
- Insulin, 10 units IV, plus glucose, 1 ampule of D<sub>50</sub> IV
- Sodium bicarbonate, 1 ampule IV
- Inhaled albuterol: continuous nebulization
- Magnesium sulfate, 2 g IV

Reduce total-body potassium
- Oral polystyrene sulfonate (Kayexalate)
- Dialysis

D<sub>50</sub>, 50% dextrose; IV, intravenously.
factors for cardiovascular disease. Renal failure does not change the treatment of acute myocardial infarction.

Other causes of life-threatening chest pain should be considered. Patients with renal failure have abnormalities in platelet adhesion that make pulmonary embolism more likely.

**Uremic Pericarditis** Uremic pericarditis may occur in patients with a high blood urea nitrogen level. Classic findings of chest pain, pericardial friction rub, worsening of pain when supine, and ECG changes may or may not be present. The presence of any of these signs should trigger a differential diagnosis that includes uremic pericarditis. If no signs of pericardial tamponade are present, pain control and hospital admission are appropriate. Uremic pericarditis traditionally prompts the initiation of dialysis in patients not already receiving renal replacement therapy.

Dialysis-associated pericarditis can also occur. It is not well understood, but large effusions may be present and require either increased dialysis or surgical correction.7

**Pericardial Tamponade** Many patients with long-standing renal failure have preexisting pericardial effusions and volume overload that complicate the diagnosis of pericardial tamponade. Chest radiography may not reveal classic abnormalities in heart shape because many patients may have coincident cardiomegaly. Echocardiographic findings may also be altered.8

**Hemorrhage** Prolongation of the bleeding time, decreased activity of platelet factor 3, abnormal platelet aggregation, and impaired prothrombin consumption contribute to the abnormal hemostasis in patients with renal failure. Patients may have abnormal bleeding as a result of minor wounds or surgery, epistaxis, spontaneous gastrointestinal bleeding, or hemorrhage in the liver, pericardial sac, or brain. Gastrointestinal bleeding is both more common and more severe in patients being maintained on renal replacement therapy.9 Patients with renal failure may have preexisting anemia, and therefore small drops in hemoglobin may be detrimental. Blood transfusions that maintain the hematocrit above 30% have been shown to improve platelet dysfunction. Desmopresin, erythropoietin, cryoprecipitate, and conjugated estrogens may all be of benefit (Box 114.7).

**Infection** Both immunomodulators and cellular components of the immune system are altered in patients with renal failure and lead to a greater risk for infections. Vascular grafts, recurrent needlesticks, and peritoneal ports break the skin’s protective barrier down and offer more opportunities for bacteria to enter the circulation. Patients undergoing peritoneal dialysis are at risk for peritonitis. Most infections are bacterial. Patients often need to be treated with coverage for hospital-acquired pathogens; pneumonia in a dialysis patient is treated as a health care–associated pneumonia with broad empiric antibiotic coverage. Fever in a dialysis patient with an indwelling line should be assumed to be bacteremia until proved otherwise, and empiric antibiotic coverage for line-associated infections should be initiated. The catheter may also need to be removed. *Pseudomonas*, methicillin-resistant *Staphylococcus aureus*, and vancomycin-resistant *Enterococcus* should all be treated with appropriate antibiotics until cultures allow more specific treatment.

**COMPLICATIONS OF RENAL REPLACEMENT THERAPY**

Renal replacement therapy produces its own unique set of complications. Patients with grafts and fistulas may have infections, bleeding, or thrombosis of their access sites. Port malfunction, infection, or peritonitis may develop in peritoneal dialysis patients. Dialysis-related complications include hypertension and disequilibrium syndrome (refer to Chapter 116 for a detailed discussion of dialysis-related emergencies).

**CONSULTATION**

Urgent nephrology consultation should be obtained for patients with volume overload or significant electrolyte abnormalities requiring dialysis. Indications for dialysis are summarized in Boxes 114.8 and 114.9.

---

**BOX 114.7 Interventions to Reduce Bleeding in Patients with Renal Failure**

Packed red blood cell transfusions
Conjugated estrogens
• 0.6 mg/kg/day intravenously for 5 consecutive days or 25 mg orally or 50 to 100 mcg/24 hr transdermally every three days
Intensification of the dialysis regimen
Recombinant erythropoietin
Desmopressin (DDAVP)
• 0.3 mcg/kg (intravenously, subcutaneously, or intranasally)
Cryoprecipitate

**BOX 114.8 Indications for Dialysis in Patients with Chronic Renal Failure**

Pericarditis or pleuritis
Uremic encephalopathy or seizures
Significant bleeding secondary to uremic platelets
Fluid overload refractory to diuretics
Hypertension poorly responsive to antihypertensive medications
Metabolic disturbances refractory to medical therapy
Persistent nausea and vomiting
Evidence of malnutrition

**BOX 114.9 Indications for Dialysis in Patients with Acute Kidney Disease**

Acute volume overload in patients with pulmonary edema and significantly compromised pulmonary function
Hyperkalemia with compromising dysrhythmia, widened QRS complex, or other worrisome electrocardiographic finding
Symptomatic uremia (encephalopathy, emesis)
Severe metabolic acidosis
Severe hyponatremia
Uremic myopericarditis
A urology consultation should be initiated if the cause of the renal failure is thought to be obstruction. In cases of easily reversible outflow obstruction, the consultation can be delayed and deferred to the admitting physician’s discretion. If renal function improves and the patient is able to urinate independently without a catheter in place, outpatient follow-up with a urologist may be all that is required.

A pharmacist may also be consulted to determine renal dosing of drugs based on the patient’s creatinine clearance. In general, a single dose of antibiotics given in the ED does not need to be adjusted; subsequent doses can be adjusted by a pharmacist based on blood levels and the patient’s renal function. However, if the patient is to be sent home on medication, doses may need to be adjusted with the help of a pharmacist.

Patients undergoing peritoneal dialysis in whom peritonitis is suspected should be managed in conjunction with a nephrologist; if well appearing with normal vital signs, discharge with intraperitoneal antibiotics and close follow-up is a reasonable option.

**PITFALLS**

EPs should be vigilant for volume overload, iatrogenic overdosing of renally cleared drugs, and failure to identify hyperkalemia. Normal ECG findings do not exclude hyperkalemia. Hyperkalemia should always be investigated as the cause of arrhythmias or bradycardia in a patient with known renal failure.

**PROGNOSIS**

The prognosis of an individual patient with renal failure depends on a multitude of factors—the underlying cause of the renal failure, the patient’s preexisting renal function, and comorbid conditions. In patients with chronic kidney disease, the mortality rate, especially from cardiovascular causes, is much higher than in the general population and worsens as kidney function decreases.3

**NEXT STEPS IN CARE**

**ADMISSION VERSUS DISCHARGE**

A small subset of patients may be discharged home safely. Those undergoing chronic dialysis who are stable, have no life-threatening electrolyte abnormalities, and otherwise have no indications for admission may be discharged to follow-up with their regularly scheduled dialysis appointment.

The majority of patients with acute or acute on chronic kidney injury will require admission to the hospital. Stable patients may be admitted to non–critical care units; patients with significant volume overload or ECG changes, patients in respiratory distress, those with altered mental status, or patients who have experienced a life-threatening arrhythmia should be admitted to an intensive care unit. All dialysis patients with an indwelling catheter and a fever should be admitted to the hospital for intravenous antibiotics because of the high risk for line infection.

Patients undergoing peritoneal dialysis in whom peritonitis is suspected should be managed in conjunction with a nephrologist; if well appearing with normal vital signs, discharge with intraperitoneal antibiotics and close follow-up is a reasonable option.

**PITFALLS**

EPs should be vigilant for volume overload, iatrogenic overdosing of renally cleared drugs, and failure to identify hyperkalemia. Normal ECG findings do not exclude hyperkalemia. Hyperkalemia should always be investigated as the cause of arrhythmias or bradycardia in a patient with known renal failure.

**PROGNOSIS**

The prognosis of an individual patient with renal failure depends on a multitude of factors—the underlying cause of the renal failure, the patient’s preexisting renal function, and comorbid conditions. In patients with chronic kidney disease, the mortality rate, especially from cardiovascular causes, is much higher than in the general population and worsens as kidney function decreases.3

Emergency Renal Ultrasonography

Mark W. Byrne, Heidi H. Kimberly, and Vicki E. Noble

**INTRODUCTION**

Acute flank pain is a common complaint in the emergency department. The presence of unilateral flank or groin pain, especially in the setting of gross or microscopic hematuria, raises clinical suspicion for renal colic secondary to an obstructing ureteral stone. Bedside renal ultrasonography is a rapid and safe imaging modality for evaluation of renal colic. The presence of unilateral hydronephrosis in the correct clinical context is often sufficient to make the diagnosis. Because pain from a rapidly expanding or leaking abdominal aortic aneurysm (AAA) can masquerade as renal colic, additional evaluation of the aorta should be considered, especially in patients with risk factors for AAA.

Acute urinary retention is a common cause of abdominal pain. Bedside ultrasound is a rapid, noninvasive diagnostic tool for the evaluation of suspected urinary retention. Sonographic estimation of urinary bladder volume provides an accurate quantitative assessment of retention in the emergency setting. Additionally, screening ultrasound for the presence of adequate urine volume has been shown to decrease the number of unsuccessful attempts at catheterization in the pediatric population.

**EVIDENCE-BASED REVIEW**

Computed tomography (CT) currently has the greatest sensitivity and specificity of imaging modalities used for the diagnosis of renal colic. When compared with ultrasound, non–contrast-enhanced CT is more sensitive in identifying obstructing ureteral stones1–4 and more accurate in measuring stone size.5,6 CT also more consistently locates the specific site of obstruction along the course of the ureter and can identify other causes of abdominal pain that may mimic acute renal colic.

However, routine use of CT for suspected renal colic has significant limitations. Patients are exposed to significant amounts of ionizing radiation when they undergo CT of the abdomen and pelvis,6,7 which makes CT inadvisable during pregnancy and less appealing in the pediatric population. Because renal colic is a recurrent diagnosis, patients may eventually receive multiple CT scans over time, and cumulative radiation doses may rise to concerning levels8 and place patients at risk for cancer later in life. Additionally, radiologic imaging has been shown to be the largest contributor to the cost of hospitalization in patients with renal colic, with CT being the most expensive imaging modality.9,10

Ultrasound offers a safe, noninvasive means of assessing for renal colic that does not subject the patient to any ionizing radiation. Traditionally, ultrasound has been thought to have only fair sensitivity (37% to 64%) for detecting stones and better sensitivity (74% to 85%) for the diagnosis of acute obstruction,1 whereas CT has consistently shown sensitivity greater than 90% for the diagnosis of ureteral stones.1–4 Recent studies using modern ultrasound equipment in the hands of skilled operators have demonstrated comparable sensitivity (76% to 98%) of ultrasound for the detection of ureteral stones.11–14 Although specific stone location and size cannot always be determined with ultrasound, surrogate findings may have prognostic value in guiding patient management. One study showed that normal renal ultrasound findings in the setting of suspected renal colic predicted a very low risk (0.6%) for subsequent urologic intervention.15

The goal of bedside ultrasound is to identify unilateral hydronephrosis as an indirect sign of obstructing ureteral...
stones. In the emergency department setting, Rosen et al. demonstrated a sensitivity of 72% and specificity of 73% for the detection of hydronephrosis with bedside ultrasound. More recently, Gaspari and Horst reported a sensitivity of 87% and specificity of 85% for the diagnosis of hydronephrosis. These results are comparable to a sensitivity of 81% and specificity of 92% for bedside ultrasound performed by on-call urologists; however, this study evaluated other renal findings in addition to hydronephrosis. Although the specific size of the obstructing stone is not typically demonstrated on bedside ultrasound, the degree of hydronephrosis may correlate with the size of the obstructing stone. A 2010 study showed that no or mild hydronephrosis predicted smaller late with the size of the obstructing stone. A 2010 study showed that no or mild hydronephrosis predicted smaller stone size (<5 mm) as opposed to moderate or severe hydronephrosis.

Bedside ultrasound for the measurement of urinary bladder volume has been well described in the literature. Bedside ultrasound provides a quantitative assessment of bladder volume when evaluating for urinary retention in the emergency department setting and can guide the need for emergency catheterization. Many studies have shown good correlation between sonographic bladder volume calculations and urine volumes obtained via catheterization. In the pediatric population, ultrasound has been shown to predict patients with volumes sufficient for successful catheterization of urine samples (>3 mL). This may help avoid multiple attempts at urinary catheterization, which can result in unnecessary patient discomfort and the potential for iatrogenic infection. Additionally, bedside ultrasound has demonstrated increased success rates during attempts at suprapubic aspiration when compared with traditional, landmark-based techniques.

**HOW TO SCAN**

Emergency renal ultrasonography is performed with a 2- to 5-MHz curvilinear transducer. When rib shadows limit adequate sonographic windows for the kidneys, switching to a phased-array probe may be helpful. In general, patients can be positioned supine for renal ultrasound. The right lateral recumbent position may be necessary when imaging the left kidney because this kidney tends to be located more posteriorly and the spleen is not as large an acoustic window as the liver.

For the right kidney, the probe is initially placed along the lower portion of the rib cage in the midaxillary line with the probe marker directed toward the patient’s head. The resulting coronal view is the traditional right upper quadrant view of the focused assessment with sonography for trauma (FAST) examination. The kidney lies in a plane oblique to the long axis of the body, and the probe usually needs to be rotated slightly counterclockwise to obtain a maximally longitudinal view of the kidney (Fig. 115.1, A). This orientation also helps the ultrasound transducer align the image in between the ribs, thus minimizing rib shadows. The transducer should then be angled anterior to posterior so that it fans through the entire kidney. To obtain a transverse view of the kidney, the probe is rotated 90 degrees in a counterclockwise direction (Fig. 115.1, B). The transducer should then be fanned superior to inferior to image the entire kidney in the transverse plane.

For the left kidney, the probe is initially placed along the lower part of the rib cage in the posterior axillary line with the probe marker directed toward the patient’s head. The resulting coronal view is the traditional left upper quadrant view of the FAST examination. The transducer often needs to be moved relatively posterior and superior with respect to the right side to obtain adequate views of the left kidney. The spleen is not as large an acoustic window as the liver, and bowel gas from the stomach and colon may interfere with images of the left kidney. When a satisfactory sonographic window is located, the probe should be rotated slightly clockwise to maximize the longitudinal view of the kidney and align the transducer in between the ribs. The transducer should then be angled anterior to posterior to fan through the entire kidney. To obtain a transverse view of the kidney, the probe is rotated 90 degrees in a counterclockwise direction. The transducer should then be fanned superior to inferior to image the entire kidney in the transverse plane.

To image the urinary bladder, the transducer is placed in the midline above the symphysis pubis with the probe marker directed toward the patient’s head. The resulting sagittal view is the traditional pelvic view of the FAST examination. The transducer should then be moved or angled to the right and left to image the entire bladder. To obtain a transverse view...
of the bladder, the probe is rotated 90 degrees counterclockwise so that the probe points toward the patient’s right. The transducer should then be moved or angled superior and inferior to image the entire bladder.

When measuring urinary bladder volume, the bladder should first be imaged in the transverse plane at the level where the largest view of the bladder is obtained. The image is frozen, and bladder depth and width are measured (Fig. 115.2, A). The bladder is then imaged in the sagittal plane, again at the level where the largest view of the bladder is obtained. The image is frozen, and bladder height is measured (Fig. 115.2, B). Bladder volume can be estimated with the simplified formula 0.75 × depth × width × height. On many ultrasound machines, software will automatically calculate bladder volume by using measurements obtained by the sonographer.

It is best visualized on longitudinal images of the kidney. Hydronephrosis may be graded as mild, moderate, or severe. Mild hydronephrosis is defined as dilation of the renal pelvis and blunting of the normally concave renal calices. Anechoic areas will appear in the normally hyperechoic renal sinus as fluid fills and distends the renal pelvis (Fig. 115.3, A). Mild hydronephrosis may be difficult to appreciate on bedside ultrasound. Careful comparison with the contralateral kidney can help reveal more subtle cases of unilateral hydronephrosis. Prominent renal vessels within the renal sinus may be mistaken for mild hydronephrosis. Application of color flow or power Doppler can help differentiate whether an anechoic space within the renal sinus is due to blood vessels or actual dilation of the renal pelvis. Moderate hydronephrosis is defined as more prominent dilation of the renal pelvis and rounding of the renal calices (Fig. 115.3, B). Severe hydronephrosis is defined as extreme calyceal distention causing thinning of the renal cortex (Fig. 115.3, C). When chronic, hydronephrosis can result in a marked degree of cortical atrophy. In the setting of acute obstruction, calyceal rupture may occur and result in a urinoma. A urinoma appears as a stripe of anechoic free fluid surrounding a portion of the kidney.

Kidney stones appear as brightly echogenic structures and will exhibit posterior acoustic shadowing when sufficient size has been attained. Obstructing ureteral stones are not typically visualized directly during bedside ultrasonography. Non-obstructing stones within the renal pelvis are more frequently visualized, although they may be hard to distinguish from adjacent hyperechoic fibrofatty tissue within the renal sinus. Obstructing stones may occasionally be visualized at the ureteropelvic or ureterovesical junction. Obstructing stones within the remainder of the ureter are more challenging to identify because of overlying bowel gas. The ureters themselves are not discernible during bedside ultrasonography unless significantly dilated.

Renal cysts appear as rounded anechoic structures with thin, smooth walls and exhibit posterior acoustic enhancement (Fig. 115.4). Though not a primary indication for performing emergency renal sonography, renal cysts are not an uncommon finding and occur in roughly 50% of patients 50 years or older. When internal echoes, septations, or thick walls are visualized, other diagnoses, such as a hemorrhagic cyst, renal
Ultrasound serves as a valuable initial screening examination in patients suspected of having renal colic. It can be performed directly at the bedside by the emergency physician to rapidly categorize the likelihood of an obstructing ureteral stone. Though not specifically studied in the setting of renal colic, bedside ultrasound has been shown to expedite patient care and decrease length of stay in the emergency department when performing other focused studies\(^34,35\). Bedside ultrasound may also speed the identification of life-threatening conditions such as a leaking AAA when being considered in the differential diagnosis\(^36\).

In patients with clinical findings suggestive of renal colic, especially in those with microscopic or gross hematuria, the presence of unilateral hydronephrosis may be adequate evidence of a ureteral stone. If findings on the initial bedside ultrasound are normal, it may be repeated after a period of hydration, which can subsequently reveal hydronephrosis. When mild to moderate hydronephrosis is identified as a surrogate for an obstructing ureteral stone, the patient may undergo standard treatment of renal colic. When severe hydronephrosis is seen as a new finding, comprehensive imaging by radiology and urgent urologic consultation are advised\(^20,21\). Ultrasound may be especially helpful in patients with known renal colic who have recurrent or worsening pain. In these patients, in whom the diagnosis of renal colic has already been established, ultrasound is an excellent tool to screen for significant obstruction and assess for complications of obstructing stones, such as calyceal rupture and resultant abscess, or carcinoma, are more likely. Making these diagnoses is outside the scope of bedside ultrasonography, and such findings should prompt comprehensive radiologic imaging. Additionally, any structure that distorts the normal renal architecture is concerning for malignancy. Renal cancers and pseudoaneurysms may have an appearance similar to simple renal cysts\(^33\), and it is recommended that color flow or power Doppler be applied to evaluate for internal blood flow within any cystic structure seen in the kidneys.
urinoma. In comparison, patients with complicating comorbid conditions such as a solitary kidney, known abdominal or pelvic tumor, or recent instrumentation should not be assessed solely with bedside ultrasound. These patients are more likely to have ureteral obstruction unrelated to renal colic, and the presence of unilateral hydronephrosis should not be interpreted as a surrogate for ureteral stones. Of note, mild unilateral (commonly on the right) or bilateral hydronephrosis may be a normal finding during pregnancy because the enlarging uterus exerts a mass effect on the ureter.

Bilateral hydronephrosis carries a completely distinct differential diagnosis and is rarely due to kidney stones. Identification of unilateral hydronephrosis should always prompt an evaluation of the contralateral kidney to rule out the presence of bilateral hydronephrosis. Bilateral hydronephrosis is typically caused by bladder outlet obstruction. In men, bladder outlet obstruction most commonly results from prostate enlargement. Neurogenic bladder, obstructing bladder clot, and prolonged urinary retention of any origin also may lead to bilateral hydronephrosis. Ultrasound evaluation of the bladder should always follow when bilateral hydronephrosis is identified.

Bedside ultrasound serves as a straightforward examination for the presence of a distended bladder when urinary retention is clinically suspected. A grossly enlarged bladder after the patient attempts to void indicates the need for urinary catheterization. In contrast, a collapsed bladder in the setting of suspected urinary retention should prompt a search for alternative diagnoses. Intermediate bladder sizes necessitate calculation of bladder volume with sonographic measurements. Although threshold values for what constitutes an elevated postvoid residual urine volume are poorly defined, a volume greater than 100 mL in the setting of symptoms of obstruction (urgency, frequency, hesitancy, decreased flow) is generally used as the lower threshold for acute urinary retention. It is important to remember that urinary retention, especially when prolonged, may lead to bilateral hydronephrosis, and ultrasound evaluation of the kidneys should reflexively follow identification of a distended bladder.

In the pediatric population, bedside ultrasound may guide the timing of urinary catheterization. Attempts at catheterization are unsuccessful in obtaining urine from pediatric patients approximately 25% of the time. A brief ultrasound evaluation of the bladder identifies patients with urine volumes adequate for collecting a urine sample via catheterization. A transverse bladder dimension larger than 2 cm and a sonographic bladder volume calculation of greater than 3 mL both predict successful urinary catheterization. In cases in which suprapubic bladder aspiration is indicated to obtain a urine sample, ultrasound provides procedural guidance and increases the rate of successful bladder taps.

In summary, bedside ultrasound is a rapid, noninvasive imaging modality useful for the evaluation of flank pain. It may identify hydronephrosis as a surrogate finding in patients with renal colic and can be used to exclude AAA from the differential diagnosis. Ultrasound can also assist in the diagnosis of urinary obstruction and provide guidance for the timing of urinary catheterization in children. Emergency renal sonography is a focused application that must be interpreted within the clinical context of the patient’s signs and symptoms. Patients with findings outside the scope of the bedside ultrasound examination should be referred for consultative radiologic imaging.

Dialysis-Related Emergencies

Yi-Mei Chng and Gregory H. Gilbert

Connecting an artery (usually in the forearm) directly to a vein via surgery creates a native AV fistula (Fig. 116.1). Over months, the increased blood flow creates a larger, stronger vein with adequate blood flow for dialysis. Native AV fistulas are less likely than other forms of hemodialysis access to become infected or form clots.

Synthetic AV grafts (Fig. 116.2) are used when forearm veins are unsuitable for native grafts. Synthetic grafts can be used within weeks of placement; however, they have higher infection and clotting rates than native AV fistulas do.

Central venous catheters (Fig. 116.3) are used when dialysis access is needed before permanent AV grafts have had time to mature or when fistula or graft surgery fails. Approximately 25% of the hemodialysis patients in the United States use central venous catheters as their primary vascular access. Tunneled, cuffed catheters have a lower infection rate than nontunneled catheters do. All these catheters have a double lumen and are at higher risk for infection and clotting than AV fistulas or grafts are.

**KEY POINTS**

- Infection is a common cause of morbidity and mortality in dialysis patients. Tunneled lines and temporary dialysis catheters are more likely to become infected than grafts and native arteriovenous fistulas.
- The differential diagnosis of hemodynamic instability in a hemodialysis patient is dependent on the associated signs or symptoms (e.g., fever, chest pain), as well as the duration and speed of onset of the instability.
- Early vascular surgery consultation is necessary for patients with clotted hemodialysis access.
- Peritonitis is a common infection associated with peritoneal dialysis. Turbidity is one of the earliest signs of infection.
- Empiric treatment of peritoneal dialysis-associated peritonitis should include intraperitoneal antibiotics with both gram-positive and gram-negative coverage.

**SCOPE**

In the United States, in excess of 380,000 patients with renal failure rely on some form of dialysis as life-sustaining renal replacement therapy. More than 90% of these patients are managed with hemodialysis, whereas about 7% use peritoneal dialysis (PD). The most common complication associated with either dialysis modality is infection, although many access site malfunctions and dialysis-related emergencies prompt visits to the emergency department (ED) by this population.

**HEMODIALYSIS**

**STRUCTURE AND FUNCTION**

Hemodialysis can be performed through native arteriovenous (AV) fistulas, prosthetic AV grafts composed of polytetrafluoroethylene, tunneled (PermCath) central venous catheters, and nontunneled (temporary) central venous catheters. Different modalities offer different advantages.

Connecting an artery (usually in the forearm) directly to a vein via surgery creates a native AV fistula (Fig. 116.1). Over months, the increased blood flow creates a larger, stronger vein with adequate blood flow for dialysis. Native AV fistulas are less likely than other forms of hemodialysis access to become infected or form clots.

Synthetic AV grafts (Fig. 116.2) are used when forearm veins are unsuitable for native grafts. Synthetic grafts can be used within weeks of placement; however, they have higher infection and clotting rates than native AV fistulas do.

Central venous catheters (Fig. 116.3) are used when dialysis access is needed before permanent AV grafts have had time to mature or when fistula or graft surgery fails. Approximately 25% of the hemodialysis patients in the United States use central venous catheters as their primary vascular access. Tunneled, cuffed catheters have a lower infection rate than nontunneled catheters do. All these catheters have a double lumen and are at higher risk for infection and clotting than AV fistulas or grafts are.

**COMPLICATIONS**

**INFECTION**

Infectious complications are among the foremost causes of morbidity and mortality in hemodialysis patients. The risk for infection results from both impaired immune function related to the renal failure (e.g., altered granulocyte function in uremia) and repetitive access of the vasculature across the protective skin barrier. Vascular access is the source of bacteremia in 48% to 73% of infected hemodialysis patients.

Clinical findings may include fever, hypotension, altered mental status, skin infection at the access site, and severe sepsis. Patients with diabetes may have ketoacidosis. The differential diagnosis of the various clinical findings in hemodialysis patients is described in Table 116.1.

Antimicrobial therapy for potential infections related to hemodialysis access (whether catheter or graft) should cover gram-positive species, including methicillin-resistant *Staphylococcus aureus* (MRSA) and gram-negative species. Gram-positive species account for up to two thirds of the infections whereas gram-negative species account for the remainder. Broad-spectrum antibiotic coverage should be initiated empirically until the results of culture are available, especially in patients with diabetes or other risk factors for infection.
SECTION XI  Genitourinary and Renal Diseases

Table 116.1  Differential Diagnosis of Various Clinical Findings in Hemodialysis Patients

<table>
<thead>
<tr>
<th>Clinical Finding</th>
<th>Differential Diagnosis and Critical Actions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hypotension</td>
<td>If accompanied by fever, consider sepsis. If sudden onset during dialysis, consider hypovolemia secondary to excessive ultrafiltration, anaphylaxis or anaphylactoid reaction, or air embolism. If accompanied by chest pain, consider tamponade, arrhythmia, or acute coronary syndrome.</td>
</tr>
<tr>
<td>Altered mental status</td>
<td>If onset immediately after first hemodialysis session, consider dialysis disequilibrium syndrome. If the onset is gradual, consider dialysis dementia. Infection is a common cause of altered mental status (delirium) in hemodialysis patients, and the presence of a fever should prompt antibiotic administration and a search for the source. Also consider stroke, hypotension, drug effect, seizure, and metabolic derangement (acidosis, hyperkalemia).</td>
</tr>
<tr>
<td>Chest pain</td>
<td>Consider acute coronary syndrome, pulmonary embolism, air embolism, uremic pericarditis, and arrhythmias caused by electrolyte imbalance.</td>
</tr>
<tr>
<td>Shortness of breath</td>
<td>Consider fluid overload, cardiac tamponade, acute coronary syndrome, air embolism, and anaphylactoid reactions.</td>
</tr>
<tr>
<td>Bleeding</td>
<td>Bleeding can be due to excessive anticoagulation during dialysis or uremic coagulopathy.</td>
</tr>
<tr>
<td>Fever</td>
<td>Consider line infection in patients with warmth or erythema of the skin overlying the dialysis access site. Consider sepsis if the patient is hypotensive or in shock; obtain blood for culture and administer antibiotics. Fever is almost always due to infection, but overheated dialysate is a potential cause.</td>

</table>

who have a history of gram-negative bacteremia or who may be septic from a secondary source. The recommended regimen is 1 g of vancomycin intravenously (with sequential doses according to the level of the drug at dialysis) plus gram-negative coverage with either an aminoglycoside or a third-generation cephalosporin.

Removal or exchange of an infected catheter is advisable because a bacterial biofilm can form rapidly in the lumens of most indwelling central venous catheters and serve as a source of continued infection. Systemic antibiotics given alone are relatively ineffective in eradicating infection if the catheter is not removed. There are occasional protocols that have demonstrated catheter salvation, but none have done so reliably. Catheter removal with delayed replacement is
required in patients who are clinically unstable, who have metastatic infectious complications, or who have tunnel infections. Tunneled catheters can be replaced with temporary nontunneled catheters or can be changed over a guidewire, thus avoiding disruption of the patient’s dialysis schedule.

**THROMBOSIS**
Thrombosis of hemodialysis access grafts and catheters is a significant cause of morbidity. Failure of hemodialysis grafts is mainly due to progressive intimal hyperplasia at the venous anastomosis and resultant decreased flow and graft thrombosis.4

Signs and symptoms of impending graft thrombosis include loss of the thrill or bruit, increased water-hammer pulses, increased venous pressure, and poor flow rates.

Success of treatment decreases with time. A vascular surgeon should be consulted immediately for definitive treatment with thrombectomy (percutaneous or surgical) or surgical revision. To avoid rupture or distal embolization, the access site should not be forcibly irrigated or manipulated.

Thrombolytic agents can be initiated in consultation with a vascular surgeon. Several different thrombolytic regimens can be used. One protocol involves the use of 2 to 4 mg of alteplase infused through an 18- to 22-gauge intravenous line while waiting for the availability of angiography. If the wait time exceeds 30 minutes, an additional 2 mg is given.5 Care must be taken to confirm that the intravenous tubing has actually been inserted into the graft pointing toward the occlusion and not into surrounding tissue or another vessel before infusion of the thrombolytic agent. The arterial limb of the graft should also be occluded while the thrombolytic agent is being infused.

**BLEEDING**
Bleeding from dialysis puncture sites or around tunneled catheters can occur hours after hemodialysis is complete. Bleeding from needle hole punctures can usually be controlled with firm (but nonocclusive) direct pressure on the site. A thrill should be documented after the bleeding stops in peripheral hemodialysis grafts. Surgicel may be placed around the entry port of a tunneled catheter to promote hemostasis. Patients should be evaluated for significant blood loss and observed in the ED to ensure that rebleeding does not occur. If the bleeding cannot be controlled or if skin erosion has occurred, a vascular surgeon should be consulted.

Hemodialysis patients are at risk for hemorrhage from other sites because of anticoagulation during dialysis. Platelet dysfunction secondary to uremia also contributes to hemorrhage in patients with renal failure, and it is only partially corrected by hemodialysis. Administration of desmopressin (DDAVP) (0.3 mcg/kg intravenously with 50 mL saline over a 3-minute period, 0.3 mcg/kg subcutaneously, or 2 mcg/kg intranasally) improves the hemostatic function of platelets and is useful in treating hemorrhage in hemodialysis patients. The maximal effect of DDAVP occurs after 1 hour, and if immediate hemostasis is needed, 10 units of cryoprecipitate can be infused over a 30-minute period.4

**PSEUDOANEURYSM**
Pseudoaneurysms are more likely to occur with prosthetic grafts, but they can also develop with autogenous access. Duplex ultrasound can be used to distinguish between pseudoaneurysms and other perigraft fluid collections. Small puncture site pseudoaneurysms can sometimes be monitored, but pseudoaneurysms at the anastomosis of the graft require surgical or endovascular revision and are often associated with infection. Vascular surgery consultation is necessary for suspected pseudoaneurysms.4

**DIALYZER REACTIONS**
Patients undergoing their first hemodialysis session or those switching to a new dialyzer may experience anaphylaxis or an anaphylactoid reaction to a component of the dialyzer or dialysate. Anaphylactoid reactions have been observed with dialyzers made of cuprophane and with polyacrylonitrile dialysis membranes (particularly in patients taking angiotensin-converting enzyme inhibitors). Treatment consists of epinephrine, antihistamines, and steroids.6

**AIR EMBOLISM**
Venous air embolism is a rare complication of hemodialysis that can occur during a session or during insertion of (or more
Peritoneal dialysis catheters.

pressure of cuff a your not blood placement on allow

cases can be treated by raising serum osmolarity with usually self-limited and resolve within a few hours; severe

shifts in serum osmolarity during dialysis. Symptoms are which results in cerebral edema.

larity in the brain. This leads to the rapid ingress of free water, such as urea from serum causes a rapid drop in serum osmo-
larity and pH during dialysis. Removal of small solutes believed to result from cerebral edema caused by shifts in

osmolarity during hemodialysis) or as an exacerbation of volume over-
load in the setting of a preexisting effusion. Hemodynamically
compromised patients with significant pericardial effusions
are not clinically significant. Symptomatic cardiac tamponade
occurs during or immediately after hemodialysis. In severe
cases, patients may exhibit altered mental status, seizures, or
coma (although other probable causes of these altered menta-
tion states should be excluded first before attributing such
symptoms to dialysis disequilibrium syndrome).

The exact pathogenesis of the syndrome is unclear; it is
believed to result from cerebral edema caused by shifts in
osmolarity and pH during dialysis. Removal of small solutes
such as urea from serum causes a rapid drop in serum osmo-
larity in the brain. This leads to the rapid ingress of free water, which results in cerebral edema.

The mainstay of treatment is prevention by avoiding rapid
shifts in serum osmolarity during dialysis. Symptoms are
usually self-limited and resolve within a few hours; severe
cases can be treated by raising serum osmolarity with

infusions of hyperosmolar solutions such as hypertonic saline
or mannitol, in consultation with a nephrologist.11

DIALYSIS DEMENTIA
Dialysis dementia is a form of dialysis-related encephalopathy
that is associated with dyspraxia and multifocal seizures. Unlike
dialysis disequilibrium syndrome, dialysis dementia is
slowly progressive in onset and generally occurs in patients
who have been undergoing hemodialysis for at least 2 years.
There are three forms of dialysis dementia:

1. An epidemic form believed to be due to contamination of
dialysate with aluminum, which is usually excreted by the
kidneys (the use of deionized water in dialysis has decreased
the incidence of this form)
2. A sporadic endemic form whose cause remains unclear
3. A pediatric form that occurs in children with renal failure
even when they have not yet undergone dialysis (this
may be related to exposure to aluminum-containing
medications)

Seizures in the ED should be treated with benzodiazepines;
a serum aluminum level should be obtained in addition to
performance of other standard laboratory tests if dialysis
dementia is suspected (see Table 116.1).

PERITONEAL DIALYSIS

STRUCTURE AND FUNCTION

PD can be performed in a number of different ways; however,
the complications associated with the various methods are
similar. Typically, PD is performed with a Tenckhoff catheter
(it can be straight or curved, single or dual cuffed) inserted in
a median or paramedian line with or without omentectomy.
Omentectomy is associated with fewer complications. The
dialysate is infused into the abdomen via either a pump or
gravity. It remains in the abdomen for a period, known as the
dwell time, long enough to allow osmosis and diffusion. The
effluent (or dialysate after dwelling in the abdomen) is then
drained (Fig. 116.4).9
COMPLICATIONS

Complications of PD are organized into three groups: mechanical, infectious, and medical (Box 116.1).

The most common and life-threatening complication is peritonitis, which causes the effluent to be turbid and cloudier than usual. This symptom should not be ignored. Patients are typically afebrile and otherwise well appearing. They do not have a rigid abdomen—and instead, findings on physical examination are usually unimpressive, and the patient may at most complain of mild abdominal pain.

Peritonitis is usually the most common finding in patients with PD catheter malfunction, but other problems can arise. Blood in the effluent suggests solid organ damage (especially if the catheter was placed recently), ruptured or leaking abdominal aortic aneurysm, or coagulopathy.

MECHANICAL COMPLICATIONS

Mechanical complications are related to the process of dialysis and include pump malfunction (for patients maintained on continuous cyclic or intermittent dialysis); inability to instill the dialysate or failure of the effluent to drain because of catheter malfunction or dislodgment; or leakage of fluid into the groin, across the diaphragm, or out of the abdominal wall.

INFECTIONOUS COMPLICATIONS

Infectious complications include peritonitis, cellulitis at the catheter site, infection in the tunnel site itself, or intraabdominal abscesses.

MEDICAL COMPLICATIONS

Most frequently, medical complications are related to nutrition. Hypoalbuminemia results from poor dietary intake and daily loss of 15 g of protein, which promotes infection by impairing normal immune function. Hyperglycemia occurs as a result of a large glucose load in the dialysate. Bowel obstruction can occur secondary to abdominal surgery.

Differential Diagnosis

Although peritonitis is the most common cause of fever and abdominal pain or tenderness in a PD patient, patients with other intraabdominal infections may also have these symptoms. Swelling in the groin or shortness of breath suggests leakage of the dialysate because of the high intraabdominal pressure associated with instilling 2 L of fluid. Common abdominal infections in patients undergoing PD reflect those in the general population: appendicitis, cholecystitis, pancreatitis, and small bowel obstruction.

Diagnostic Testing

MECHANICAL COMPLICATIONS

Abdominal radiography is the most important modality. Radiographs confirm that the tube is placed correctly in the true pelvis, that no kinks are present, and that the tube has not broken into multiple pieces. Chest radiographs can reveal evidence of pleural effusion, and bowel obstruction is apparent on upright and lateral decubitus abdominal views. For suspected leaks, intraperitoneal water-soluble contrast material can be instilled to demonstrate communication with noted areas of swelling.

INFECTIONOUS COMPLICATIONS

Culture is critical when testing for infectious complications. PD-associated peritonitis is defined as two of the following three: (1) signs and symptoms; (2) white blood cell (WBC) count higher than 100/mL in the PD effluent, with more than 50% neutrophils after a dwell time of at least 2 hours; and (3) positive culture of an organism from the PD effluent. For patients undergoing automated PD who are being evaluated during their nighttime treatment, the dwell time will not be 2 hours, so the percentage of neutrophils should be used for diagnostic purposes even if the absolute WBC count is not higher than 100/mL. Bacteria in the peritoneal cavity have been diluted significantly by the dialysate, which can lead to negative cultures at standard volumes. To improve diagnostic results, 50 mL of effluent should be centrifuged down and the sediment resuspended in 3 to 5 mL of sterile saline before inoculation into both solid and liquid blood culture media. Alternatively, a minimum of 10 mL of effluent per blood culture bottle can be used. Blood cultures are not helpful unless the patient appears septic.

MEDICAL COMPLICATIONS

A comprehensive metabolic panel and serum lipase level should be obtained. Liver function tests and serum lipase levels can differentiate other causes of abdominal pain. Albumin levels are useful markers of malnutrition, which is present in 40% of these patients (25% of whom are severely malnourished). Hypoalbuminemia significantly increases the incidence of morbidity and mortality, especially in patients with peritonitis and those with a serum albumin concentration lower than 35 g/L. Hypokalemia causes decreased gut motility and constipation, which is associated with peritonitis; both conditions should be treated. Hyperglycemia, inadequate dialysis, and volume depletion or overload can be evaluated by physical examination and standard laboratory testing.
MECHANICAL COMPLICATIONS

Most complications require removal of the peritoneal catheter or some type of surgical repair; patients need to be switched to hemodialysis until the catheter malfunction is resolved.

For a clogged catheter, attempts to empty the bladder and then the bowel (with laxatives) may improve function. If the catheter is clogged with fibrin or clot, heparin (500 U/L) can be added to the dialysate. If this fails, urokinase can be used as a last resort (5000 IU diluted in saline), which has a success rate of 10% to 15%.9

INFECTIOUS COMPLICATIONS

Gram-positive organisms account for three fourths of PD-associated infections, half of which are due to Staphylococcus epidermidis. Concerning organisms observed in infections are Pseudomonas, S. aureus (including MRSA), and fungal species.11

If the patient has had culture-positive results in the past, these results can help guide antibiotic therapy. Otherwise, empiric antibiotic therapy should cover gram-positive and gram-negative organisms based on local hospital sensitivities.

Intermittent or continuous antibiotic therapy can be used with continuous ambulatory peritoneal dialysis (Table 116.2). Dosing regimens are different for patients undergoing automated PD. For intermittent treatment, antibiotics are added to only one of the four daily exchanges. For continuous therapy, a loading dose is given in the first exchange and then a

maintenance dose is given in each exchange for the remainder of the course of treatment.12

One suggested regimen is cefazolin (15 mg/kg/day intraperitoneally [IP]) for intermittent treatment, or for continuous therapy administer a 500-mg loading dose with 125-mg maintenance doses. For gram-negative coverage, an antibiotic that also treats Pseudomonas infection should be given, such as ceftazidime (1000 to 1500 mg/day IP), or for continuous therapy use a 500-mg loading dose and 125-mg maintenance doses. If MRSA infection is suspected, vancomycin (15 to 30 mg/kg) can be added to the dialysate and should be used in place of cefazolin.12 Of note, vancomycin and ceftazidime must be mixed in a dialysate solution of greater than 1 L to be compatible. Aminoglycosides should not be mixed with penicillins in an intraperitoneal infusion.11

Doses for renally excreted drugs should be increased by 25% if the patient produces more than 100 mL of urine per day.12

Fungal infections may occur after antibiotic treatment. They require early removal of the catheter and are associated with a mortality of 25%.12

Exit site infections should be treated with oral antibiotics except in some cases of MRSA.11 Therapy is guided by Gram stain of the purulent drainage and by previous treatment regimens, although S. aureus, S. epidermidis, and Pseudomonas aeruginosa are responsible for the majority of infections. For first-time infections, immediate empiric antibiotic treatment of gram-positive organisms should be initiated (cephalexin, 500 mg orally two to three times daily). Suspected MRSA infections should be treated with vancomycin, clindamycin, Bactrim, or rifampin (do not use rifampin as monotherapy). Patients with MRSA infections may also be given intranasal and local mupirocin (cream, not ointment, because the polyethylene glycol in the ointment can damage the polyurethane in some PD catheters) twice a day for 5 to 7 days. Suspected pseudomonal infections should be treated with quinolones, although double therapy in accordance with local susceptibility patterns is recommended because of the rapid rise of resistance.11 The duration of treatment is at least 2 weeks for gram-positive organisms and 3 weeks for pseudomonal organisms.

**MEDICAL COMPLICATIONS**

Management of most medical complications in PD patients is similar to that in the general population. Hyperglycemia can be treated with intraperitoneal insulin, but at higher doses.11 Hypokalemia should be treated aggressively because it leads to constipation and risk for peritonitis. Hypoalbuminemia should be managed with protein supplements and education of the patient. In severe cases, total parenteral nutrition or intravenous albumin (or both) may be necessary.10

**DISPOSITION**

**MECHANICAL COMPLICATIONS**

Patients can be safely discharged home if dialysate goes in, effluent comes out, and no signs of infection are present. If a patient is unable to use the PD catheter, hospital admission may be necessary.12

and scheduling for hemodialysis in consultation with a nephrologist are necessary.

**INFECTIOUS COMPLICATIONS**
The majority of patients with peritonitis are stable and can be treated at home. Those with fever, vomiting, intractable pain, fungal infection, or concomitant catheter site infection and those refractory to outpatient treatment require hospital admission. Discharge and urgent follow-up should be arranged with the team that placed the catheter and with the patient’s nephrologist.1

**MEDICAL COMPLICATIONS**
The disposition of patients with medical complications depends on the severity of the specific disease process. Nutritional problems can usually be managed with patient education and close outpatient follow-up.

**PATIENT TEACHING TIPS**

**Peritoneal Dialysis**
- Wear loose clothing.
- Do not submerge yourself in unchlorinated water (baths, rivers, lakes).
- Avoid heavy lifting and abdominal exercise.
- Wash your hands and peritoneal dialysis site with antibacterial soap.

Renal Transplant Complications

Gerald Maloney

KEY POINTS

- Renal transplantation is highly successful. With appropriate immunosuppressive therapy, the rate of acute rejection during the first posttransplant year is less than 25%; 1-year survival rates approach 100%.
- Surgical complications that may be seen in the emergency department include hematoma formation, ureteral anastomotic leak, and ureteral obstruction. Computed tomography is the diagnostic imaging modality of choice for these surgical emergencies.
- Surgical infections that are common in the first posttransplant month include pneumonia, line sepsis, and wound infection. Opportunistic infections reach their peak incidence during the remainder of the first posttransplant year. After the first year, community-acquired infections predominate.
- Renal transplant patients have a high risk for atherosclerotic disease. Cardiovascular conditions account for 30% to 50% of deaths during the first posttransplant year.
- Fluoroquinolones and macrolides may increase levels of cyclosporine and tacrolimus; these antibiotic classes should not be used as first-line agents for the treatment of patients with posttransplant pneumonia.
- Fever and tenderness over the graft site may indicate acute rejection.
- Transplant recipients treated with corticosteroid therapy have functional adrenal insufficiency and require pulse doses of corticosteroids when they encounter physiologic stress.

Epidemiology

The kidney is the most commonly transplanted solid organ. According to the U.S. Organ Procurement and Transplantation Network, more than 298,260 kidney transplants have been performed to date.1 It is important that providers have a general understanding of the expected surgical and medical complications commonly observed in posttransplant patients.

Developments in Renal Transplantations

The primary indication for renal transplantation is stage V chronic kidney disease (formerly called end-stage renal disease). Transplantation is recognized as the most effective form of renal replacement therapy for these patients.

Specific disease entities that causing chronic kidney disease are outlined in Box 117.1. Diabetic nephropathy is the most common single disease process leading to renal transplantation.1

Most renal grafts now function for longer than 10 years. The 1-year survival rate of renal transplant recipients is 95% to 98%. Renal transplants are more effective than hemodialysis at prolonging the life of patients with chronic kidney disease.2

Previously, the highest surgical success rates were achieved with histologically matched donor kidneys from a living recipient. Advances in immunosuppressive medication regimens have improved the success rate of cadaveric kidney transplantation, which now approaches that seen with living donors.

Preoperative clearance for renal transplantation is extensive. For patients with cancer, the suggested disease-free interval before transplantation is 5 years. Infection with human immunodeficiency virus is considered a contraindication to renal transplantation in many institutions, although transplantation has been successful in many patients with well-maintained CD4+ T-cell counts.

Cholecystectomy was previously performed in all patients undergoing renal transplantation. Currently, cholecystectomy is performed only in patients with evidence of cholelithiasis or cholecystitis.

The surgical approach to renal transplantation varies with the age of the patient, as well as with the location of the kidney and the anastomosis. The recipient’s native kidneys and collecting system are generally left in place unless there is another indication for nephrectomy. The donor kidney is placed in one of the lower abdominal quadrants (more commonly the right), and the ureter is anastomosed to the bladder; arterial and venous anastomoses generally arise from the iliac vessels, aorta, or inferior vena cava. The transplanted kidney is usually palpable on abdominal examination.

Immunosuppression is initiated after transplantation and is divided into two phases: induction and maintenance.1 Agents such as tacrolimus and monoclonal and polyclonal antibodies are often included in the induction and maintenance phases of treatment (Box 117.2). With the use of immunosuppressive medications, the 1-year incidence of acute rejection is 15% to 25%.

Complications

Complications of renal transplantation can be categorized by cause as either surgical or medical and further divided by time of occurrence as either early or delayed.
SURGICAL COMPLICATIONS
Surgical complications include graft malfunction, thrombosis, aneurysms of the graft vessels, and stricture or obstruction of the ureter. Some of these complications will be evident shortly after surgery; others may occur years after the procedure and cause symptoms that will probably prompt emergency department (ED) evaluation.

Graft function may be delayed in up to 30% of cadaveric transplants, probably as a result of prolonged cold ischemia of the kidney during the period between harvesting and transplantation. Delayed graft function is a rare complication with living donor transplants. Patients may require continued dialysis until adequate posttransplant function is demonstrated.

Acute thrombosis of the arterial or venous anastomoses is usually seen within the first posttransplant week. Treatment is surgical exploration in an attempt to salvage the donor kidney.

Renal artery stenosis has been reported in allografts and can cause hypertension in posttransplant patients. This is generally a delayed complication. Aneurysms of the graft vessels are uncommon, delayed events.

Hematomas may develop around the transplanted kidney. Hematoma formation may be an early postoperative complication or rarely may result from acute rejection with spontaneous rupture of the kidney. Acute hematomas are surgical emergencies.

Ureteral complications include anastomotic leakage (generally within the first posttransplant month), acute ureteral obstruction, and lymphoceles. These complications will occur within the first 3 months following transplantation. Computed tomography of the abdomen is the preferred imaging modality for ureteral complications. Ureteral obstruction often requires emergency surgical intervention.

MEDICAL COMPLICATIONS
Medical complications are numerous and often subtle. Posttransplant patients are at risk for atypical infections, cardiovascular death, renal failure, and rejection. Adverse reactions from immunosuppressive medications account for many delayed medical complications in transplant patients.

Fever
Management of fever in posttransplant patients should be approached similar to that of fever in other immunocompromised patients. Because of suppressed immunologic and inflammatory responses, posttransplant patients may not exhibit the common findings of acute infection. Fever may or may not be associated with clinically significant infection.

Acute rejection is one cause of fever that may develop at any time. Decisions regarding appropriate diagnostic testing and disposition of a posttransplant patient with fever should be made in consultation with a transplant service.

Infections
The incidence of infection in the first posttransplant year has been reported to be as high as 25% to 80%. Expected infections vary according to posttransplant time. Infections in the first posttransplant month are typical postoperative infections—pneumonia, sepsis from central lines or urinary catheters, and wound infections. Atypical or opportunistic infections are uncommon.

After the first month through the end of the first posttransplant year, opportunistic infections reach their peak incidence. A variety of atypical bacterial, viral, fungal, protozoal, and parasitic infections may occur. Individual transplant services maintain current information on the opportunistic infections seen in their institution. Cytomegalovirus is one of the most common opportunistic infections and occurs in up to 25% of renal transplant recipients. It can cause systemic or invasive disease and is associated with acute rejection.

After the first year, the incidence of opportunistic infections decreases and typical community-acquired pathogens predominate.

Leukocytosis is a poorly sensitive and inconsistent indicator of the source of the fever, and therefore a normal white blood cell count should not be used to exclude a potential infectious illness in a transplant patient. Peritoneal findings

**BOX 117.3 Infections in Posttransplant Patients**

**First Month After Transplantation**

- Typical postsurgical infections (pneumonia, urinary tract infection, line sepsis, wound infection)
- Opportunistic infections uncommon

**Infections in the First Posttransplant Year**

- Opportunistic infections (*Pneumocystis pneumoniae*, *Cryptococcus*, fungal infections, viral infections; highest incidence in months 2 to 6)
- Cytomegalovirus (most common)
- Tuberculosis

**Infections More Than 1 Year After Transplantation**

- Community-acquired more common than opportunistic infections
- Typical organisms causing cellulitis, pneumonia, urinary tract infections
Fluoroquinolones and macrolides may increase levels of cyclosporine and tacrolimus; these antibiotic classes should not be used as first-line agents for the treatment of patients with posttransplant pneumonia. Discussion with the transplant service may be beneficial in determining the preferred choice of antibiotic.

**Gastrointestinal Emergencies**

Abdominal pain in renal transplant recipients may be due to a variety of causes. Diagnostic imaging studies should be used liberally given the potential for patients with serious intraabdominal processes to have relatively minimal findings on physical examination. Mortality from cholecystitis is high in renal posttransplant patients. Diverticulitis is the most common bacterial gastrointestinal infectious process. Diarrhea may be due to any number of infectious organisms, including *Salmonella*, *Listeria*, *Cytomegalovirus*, and *Cryptosporidium*.

Abdominal pain in the area of the allograft should prompt consideration of acute rejection.

Opportunistic infections may affect any area of the gastrointestinal tract, from the mouth to the anus. Common opportunistic infections include candidiasis, *Cytomegalovirus*, and herpes simplex. *Cytomegalovirus* and Epstein-Barr virus can cause acute hepatitis.

Various immunosuppressive drugs can cause stomatitis, ulcerations, or acute hepatitis. Renal transplant recipients have an increased incidence of acute pancreatitis that may be related to immunosuppressive agents.

**Genitourinary and Renal Emergencies**

Renal transplant recipients are prone to the same genitourinary and renal disorders as the general population. The one truly unique renal emergency in this population is rejection.

Urinary tract infections are more severe in transplant recipients. Pylonephritis may follow a fulminant course and necessitate inpatient management. These patients often require two broad-spectrum antibiotics for adequate treatment. Aminoglycosides are nephrotoxic and should be avoided if possible.

Hematuria in renal transplant recipients may be due to infection or obstruction in the allograft or in the native kidneys; imaging studies are recommended. Hemolytic-uremic syndrome is a cause of hematuria and acute renal failure in posttransplant patients that may be related to infection (*Cytomegalovirus*), rejection, or medication toxicity (cyclosporine and tacrolimus).

Common causes of renal insufficiency normally observed in nontransplant patients should be considered when evaluating acute renal failure in posttransplant patients; rejection is a later consideration, after other, more likely causes have been excluded.

If hydronephrosis is present, ultrasound studies should be ordered to look for ureteral obstruction. Arterial Doppler imaging may be needed to evaluate the adequacy of blood flow to a graft. Obstruction of an allograft is a true surgical emergency that generally requires placement of a percutaneous nephrostomy tube.

Rejection can be acute, chronic, or acute on chronic. Acute rejection occurs in the early posttransplant period. Chronic rejection is the most common cause of renal allograft dysfunction after the first posttransplant year.
A common cause of acute renal failure in renal transplant patients is nephrotoxicity from cyclosporine or tacrolimus. Rejection may not be able to be distinguished from nephrotoxicity without a biopsy. Fever and tenderness over the graft site suggest the presence of rejection, whereas elevated trough levels of cyclosporine or tacrolimus suggest drug-induced nephrotoxicity.

If acute rejection is the most likely diagnosis, the transplant service should be consulted for inpatient management and high-dose methylprednisolone therapy begun at 500 to 1000 mg daily.

### Endocrine and Metabolic Emergencies

Transplant recipients receiving corticosteroid therapy have functional adrenal insufficiency and require pulse doses of corticosteroids when they encounter physiologic stress. Stress-dose hydrocortisone should be administered to transplant patients with unexplained or refractory hypotension unless they have not been taking corticosteroids for more than 6 months.

Electrolyte disorders, especially hyperkalemia, are common in posttransplant patients as a result of cyclosporine- or tacrolimus-induced impairment of potassium excretion. This impairment may be exacerbated by the use of potassium-sparing diuretics and angiotensin-converting enzyme inhibitors.

Cyclosporine and corticosteroids both contribute to an increased incidence of new-onset diabetes in transplant recipients.

### Neurologic Emergencies

Cryptococcal meningitis and central nervous system lymphoma are seen with greater frequency in posttransplant patients because of the immunosuppression. Patients with fever of unknown origin, headache, or altered mental status should undergo intracranial imaging and lumbar puncture as appropriate. Computed tomography scanning of the brain with and without contrast enhancement is preferable in this population to more readily identify space-occupying lesions. The risk for contrast-induced nephrotoxicity must be weighed against the benefit of diagnostic accuracy when brain lesions are suspected. Similarly, use of gadolinium-enhanced magnetic resonance imaging may be contraindicated given the risk for nephrogenic systemic fibrosis in patients with abnormal creatinine clearance.

### Adverse Drug Reactions

Immunosuppressive medications cause illness through the direct toxic effects of these drugs or through interaction with other common medications. Medication reconciliation is critical as new drug regimens become more complex.

Initial posttransplant regimens typically consist of three agents: a corticosteroid, a calcineurin inhibitor (cyclosporine, tacrolimus, sirolimus), and a purine synthesis inhibitor (azathioprine, mycophenolate mofetil). Most patients are weaned off corticosteroids in 6 months, and maintenance is continued with only two drugs.

During the initial induction phase of immunosuppression, other agents such as antithymocyte monoclonal and polyclonal antibodies are used. Because these medications are generally reserved for inpatient use, it is unusual for patients to be seen in the ED with an acute complication from these agents.

Corticosteroid therapy has many well-recognized complications. In addition to functional adrenal suppression, corticosteroids can induce diabetes, steroid psychosis, gastric ulceration, pancreatitis, changes in body habitus, and avascular necrosis.

Azathioprine is one of the oldest agents used to treat rejection. It is an alkylating agent similar to other chemotherapeutic drugs, and thus its primary toxicity is bone marrow suppression (particularly leukopenia). When given with allopurinol, increased levels of azathioprine may result in myelosuppression. Azathioprine and mycophenolate mofetil demonstrate an additive risk for myelosuppression. The hepatotoxicity from azathioprine is less than that with other agents.

Cyclosporine interacts with multiple other medications and demonstrates significant nephrotoxicity. Increased serum creatinine levels are observed in up to one third of patients taking cyclosporine. As these levels rise, cyclosporine excretion decreases and renal failure worsens. Trough measurements of cyclosporine (3 hours before the next scheduled dose) differentiate drug-induced nephrotoxicity from other causes of renal insufficiency.

Tacrolimus and sirolimus both carry a risk for multiple drug interactions and worsening nephrotoxicity. Drugs that increase the metabolism of these agents may decrease their effective serum levels and thus result in acute rejection because of inadequate immunosuppression.

### Disposition

Concerns about chronic immunosuppression, graft rejection, and multiple drug interactions make management of transplant patients among the most difficult challenges encountered in the ED. As a rule, these patients require extensive laboratory and imaging studies; there are no data to predict which of these patients can safely forgo such testing in an emergency setting. Consultation with an experienced transplant team will improve outcomes. The majority of transplant patients with serious chief complaints require hospital admission for observation and further management.

REFERENCES

Gravidity refers to the total number of pregnancies conceived, including the current pregnancy. Parity characterizes the outcome of the pregnancy, and it is further subdivided into four categories described by the mnemonic TPAL (number of term infants, preterm infants, abortions, and living children; Box 118.2).

A term pregnancy lasts from 37 to 42 weeks and is divided into trimesters. The first trimester begins at conception and lasts until the 14th week. The second trimester encompasses weeks 14 to 28, and the third trimester lasts from the 28th to the 42nd week. Infants delivered before 37 weeks are considered premature, whereas those delivered after 42 weeks are considered postterm. The due date can be estimated with the Naegle rule, which is applied by subtracting 3 months from the first day of the patient’s last menstrual period and adding 7 days to that date. First trimester ultrasound scans provide more reliable estimates of gestational age.

Emergency physicians (EPs) should consider the possibility of pregnancy in every female patient of childbearing age regardless of the chief complaint or symptoms. One study documented pregnancy in 7% of ED respondents who indicated that their last menstrual period was on time and normal and that there was “no chance” that they were pregnant. Early signs of pregnancy include missed menses, vaginal bleeding, nausea, vomiting, breast tenderness, urinary frequency, fatigue, near-syncope, and abdominal pain or bloating. Some patients may not have these symptoms or may ignore them and later go to the ED with an obviously enlarged uterus or in labor.

The physiology of breathing in pregnancy is altered by both anatomic and hormonal changes. Anatomic changes include an increase in chest diameter and circumference, as well as a rise in the level of the diaphragm. The result is a reduction in total lung capacity by 5% and functional residual capacity by 20%. In contrast, vital capacity does not change.
**BOX 118.1 Physiologic Changes in Pregnancy**

**Respiratory System**
- Reduction of total lung capacity
- Reduction of functional residual capacity
- Increased tidal volume
- Increased minute ventilation
- Decreased PaCO₂

**Hematologic and Immunologic Systems**
- Increased blood volume
- Increased plasma volume
- Decreased hemoglobin (dilutional)
- Increased procoagulation factors
- Increased white blood cell count

**Cardiovascular System**
- Increased cardiac output
- Increased heart rate
- Increased stroke volume
- Decreased systemic vascular resistance
- Decreased blood pressure

**Gastrointestinal System**
- Decreased stomach motility and tone
- Increased in gastroesophageal reflux

**Dermatologic System**
- Striae gravidarum
- Linea nigra
- Chloasma or melasma
- Spider angioma

**Urinary System**
- Increased glomerular filtration rate
- Dilation of the ureters, renal pelvis, and renal calices
- Decrease in creatinine and blood urea nitrogen

**Musculoskeletal System**
- Increased spinal lordosis
- Increased pubic ligament laxity
- Breast enlargement and tenderness

**Endocrine System**
- Increased pituitary gland size
- Glucose intolerance

**HEMATOLOGIC AND IMMUNOLOGIC SYSTEMS**

Blood volume increases during pregnancy by an average of 40% to 50% secondary to both plasma volume expansion and increased erythrocyte mass. Plasma volume increases approximately 50%, with a plateau reached at 30 weeks of gestation. Erythrocyte mass increases 20% to 30% over prepregnancy levels and peaks near term, with greater increases associated with iron supplementation. Asymmetric expansion of the plasma and erythrocyte mass results in a relative anemia, referred to as the physiologic anemia of pregnancy. Plasma expansion begins earlier than erythropoiesis but then stabilizes, with the nadir in hemoglobin concentration occurring between weeks 16 and 28. Hemoglobin levels normally do not drop below 10.5 g/dL during the nadir period and should measure 11 g/dL or higher during the remaining pregnancy.

Procoagulation factors are increased during pregnancy, whereas inhibitors of coagulation are reduced or unchanged. These changes in the coagulation cascade may serve to protect the mother against peripartum hemorrhage, but when combined with venous stasis and vessel wall injury, they predispose a patient to thromboembolic disease.

Pregnancy has been described as a state of immunodeficiency but is more accurately described as a period of modified immune response. The peripheral white blood cell count is elevated during pregnancy; it ranges from 5,110/mm³ to 12,200/mm³ during gestation and rises even higher during labor. Additionally, changes in both chemotaxis and adherence of neutrophils occur during pregnancy, as well as a shift by the immune system away from the cell-mediated immune response toward antibody-mediated immunity. This altered immune focus allows tolerance of the maternal immune system to paternal antigens but increases susceptibility to pathogens and variation in the activity of autoimmune diseases.

**CARDIOVASCULAR SYSTEM**

Changes in diaphragm position and rib cage dimension cause the heart to be displaced to the left and upward and rotated on its long axis. On radiographic studies these changes are manifested as an increase in heart silhouette in the absence of actual cardiomegaly. Likewise, this change in position is responsible for apparent left axis deviation on an electrocardiogram.

Cardiac output consistently and dramatically increases during pregnancy, with a 37% to 53% increase over prepregnancy values. This change is driven by increases in both heart rate and stroke volume. The heart rate increases 15 to 20 beats/min over prepregnancy rates, and stroke volume increases by 20% to 30%. In the later stages of pregnancy, decreased venous return as a result of compression of the inferior vena cava leads to decreased cardiac output. The highest levels of cardiac output occur in the right and left lateral positions; the lowest levels occur in the supine, sitting, and standing positions. Supine hypotension with symptoms such as dizziness, nausea, and syncope develop in a small number of pregnant patients (5% to 10%).

Despite the increase in cardiac output, the pregnancy-associated reduction in respiratory rate also remains constant, but because of a progesterone-mediated increase in both tidal volume and minute ventilation, PaCO₂ decreases to an average of 30 mm Hg. The sensation of dyspnea is increased during pregnancy.
systemic vascular resistance causes an overall reduction in maternal blood pressure. Blood pressure, like cardiac output, is dependent on position, highest when sitting and lowest in the lateral recumbent position.

**DERMATOLOGIC SYSTEM**
Striae gravidarum (“stretch marks”) occur in 50% to 90% of pregnancies during the late second or third trimester. Mechanical stretching of the skin along with hormonal changes affecting the dermis are implicated. Hormonal stimulation of melanocyte activity is responsible for the hyperpigmentation seen in as many as 90% of pregnancies.

**GENITOURINARY SYSTEM**
Changes in the urinary system during normal pregnancy include increases in kidney size, glomerular filtration rate, and renal blood flow. Additionally, dilation of the ureters, renal pelvis, and renal calices occurs as a result of mechanical compression by the expanding uterus and ovarian structures, as well as progesterone-mediated smooth muscle relaxation. The right ureter is more commonly affected than the left one, probably secondary to anatomic susceptibility. The glomerular filtration rate increases 50% over nongravid values by the end of the first trimester and is maintained throughout pregnancy. This increase and the subsequent increase in filtration fraction leads to decreases in both creatinine and blood urea nitrogen levels. The dependent edema accumulated during the day is mobilized at night, which results in increased nocturia during pregnancy. An increased incidence of glycosuria is common during pregnancy and may be unrelated to blood glucose levels or kidney dysfunction, but hematuria or proteinuria before labor should be considered pathologic.

The weight of the uterus increases from 70 to 1100 g, and intratrinitine volume increases from 10 to 5000 mL. The gradual change in color of the vaginal walls to dark blue or black (Chadwick sign) is secondary to venous congestion.

**GASTROINTESTINAL SYSTEM**
Changes in the gastrointestinal system during pregnancy include an overall decrease in gastric tone and motility. There is also a decrease in lower esophageal sphincter tone caused by altered hormone levels. This muscle relaxation, coupled with compression of the stomach by the expanding uterus, leads to an increase in gastroesophageal reflux disease. Paradoxically, a concurrent decrease in peptic ulcer disease takes place.

Liver anatomy and function are essentially unchanged. However, serum alkaline phosphatase levels are elevated during the third trimester secondary to placental production of the isoenzyme. Gallbladder emptying is slower and less efficient during pregnancy. In addition to stasis, changes in the chemical composition of bile lead to increased formation of cholesterol crystals. The result is an increase in symptomatic cholelithiasis.

**MUSCULOSKELETAL SYSTEM**
To counterbalance the expanding uterus and prevent an anterior shift in the center of gravity, the degree of lordosis of the lumbar spine increases throughout pregnancy, which often results in low back pain. Increased laxity of the ligament of the pubic symphysis and sacroiliac joints can also cause pain. Increasing tenderness of the breasts is common in pregnancy.

**ENDOCRINE SYSTEM**
Enlargement of the breasts and nipples is normal, and discharge of colostrum from the nipples during the later stages of pregnancy is not uncommon. Despite histologic changes, women remain euthyroid during pregnancy, and the slight increase in thyroid size that does occur is not clinically detectable. A palpable increase in the thyroid during pregnancy is pathologic and must be further evaluated. The results of laboratory tests commonly used to evaluate thyroid function should be within normal limits. Significant hypothyroidism during pregnancy is associated with fetal neurologic defects such as mental retardation and lower IQ scores.10,11

The pituitary gland increases 136% in comparison with its prepregnancy size. This increase in size makes the gland more susceptible to infarction with hemorrhage (Sheehan syndrome) but does not impair the optic chiasm.

Some level of glucose intolerance is associated with pregnancy. Normal pregnancy is marked by hyperglycemia after eating, followed by hypoglycemia when fasting. Postprandial hyperglycemia ensures adequate delivery of nutrients to the fetus.

**COMMON MEDICAL DISEASES AND PREGNANCY**

**DIABETES**
Diabetes occurs in approximately 3% to 5% of all gestations.12 Three types of diabetes affect pregnancy: type 1, type 2, and gestational diabetes. Gestational diabetes accounts for 90% of cases. Fetal risks during pregnancy in women with diabetes include congenital malformation, intrauterine growth retardation, macrosomia, fetal hypoglycemia, fetal respiratory distress syndrome, neonatal hypocalcemia, hyperbilirubinemia, polycythemia, intrauterine demise, and neonatal jaundice.13 These risks are greatest for women with type 1 diabetes, although type 2 and gestational diabetes are also associated with a significant increase in fetal mortality.

With tight glucose control, the perinatal mortality rate of diabetic pregnancies can approach that of uncomplicated pregnancies. However, maintaining normal blood sugar levels is extremely difficult because of the changing degree of insulin resistance throughout pregnancy.

Patients who are unable to achieve glucose control with diet and exercise require insulin therapy. The side effects of oral hypoglycemic agents in pregnant patients have not been studied extensively. Some agents may be associated with an increased rate of congenital malformation, and frequently they do not provide adequate glucose control.

Diabetic ketoacidosis occurs in as many as 10% of patients with type 1 diabetes. Treatment during pregnancy is the same as for nongravid patients but should include assessment of fetal status and supportive measures such as oxygen and use of the left lateral decubitus position to maximize fetal blood flow.

**URINARY TRACT INFECTIONS**
The incidence of acute cystitis or acute pyelonephritis is approximately 1% during pregnancy. Asymptomatic bacteriuria is a related condition in which urine culture is positive in an asymptomatic patient. The incidence of asymptomatic bacteriuria is similar in both gravid and nongravid populations,
with 2% to 10% of the population being affected. However, gravid patients have a much higher rate of progression to symptomatic infection, and as many as 40% of cases eventually progress to acute pyelonephritis. Chronic cystitis and chronic and acute pyelonephritis are associated with negative outcomes, and patients should receive antibiotic therapy. Patients with recurrent asymptomatic bacteriuria or urinary tract infection may require daily suppressive therapy or post-coital prophylaxis.

Treatment of asymptomatic bacteriuria and acute cystitis can be accomplished with 3 to 7 days of oral therapy consisting of amoxicillin, a cephalosporin, or nitrofurantoin. Unless sensitivities are known, nitrofurantoin is the preferred agent because of higher levels of resistance to the other agents. Acute pyelonephritis during pregnancy increases the risk for preterm labor and should be managed aggressively. Patients require admission and intravenous antibiotic therapy until clinical improvement is demonstrated.

**ASTHMA**

Approximately 4% of pregnancies are complicated by asthma, roughly mirroring its incidence in women of childbearing age. The course of asthma during pregnancy is not uniformly predictable. One third of patients will have improvement in their symptoms during pregnancy, one third will experience stable disease, and another third will have worsening of their symptoms. Though somewhat controversial, patients with asthma have been reported to have increased rates of preeclampsia, cesarean delivery, and preterm rupture of membranes. Fetal risks include increased mortality, prematurity, intrauterine growth retardation, and low birth weight.

Monitoring and treatment of asthma in pregnant patients are much the same as for nonpregnant patients. Commonly used measures include the peak expiratory flow rate and forced expiratory flow in 1 second. Beta-agonists are the initial medication of choice both for acute exacerbation and for maintenance. Inhaled corticosteroids are safe and effective, but intravenous corticosteroids may be required during acute exacerbations.

**SEIZURE DISORDERS**

Epilepsy is associated with an increased incidence of obstetric and fetal complications. However, more than 90% of pregnant women with epilepsy have a normal pregnancy with a good outcome. Seizure disorders affect approximately 1% of the general population and affect a similar percentage of gestations. As many as one third of women with epilepsy experience an increase in seizure activity during pregnancy. Patients with a higher pre gravid incidence of seizures are at greater risk for increased seizure frequency during pregnancy. Increased seizure activity may result from decreased compliance with medical therapy, altered pharmacologic distribution, increased elimination of medications, or a combination of factors.

Status epilepticus during pregnancy is a grave danger for both the mother and fetus and should be treated aggressively with early intubation, pharmacologic therapy, and evaluation for eclampsia. Benzodiazepines, phenytoin, and fosphenytoin are all effective in the treatment of status epilepticus. New seizure activity during pregnancy merits investigation to determine its cause; eclampsia should be suspected in the third trimester.

**NEW SEIZURE ACTIVITY**

New seizure activity during pregnancy merits investigation; eclampsia must always be suspected in the third trimester.

**HEMOGLOBIN LEVELS**

Hemoglobin levels do not normally drop below 10.5 g/dL during pregnancy and should usually measure 11 g/dL. More significant anemia should be investigated.

**PREGNANCY IS A STATE OF MODIFIED IMMUNE RESPONSE**

Pregnant women have increased susceptibility to pathogens.

**MIGRAINE**

Migraine symptoms are reduced or resolved in 60% to 80% of women during pregnancy. Acceptable pharmacologic agents to treat symptoms include acetaminophen, narcotics, and antiemetics such as prochlorperazine, promethazine, and metoclopramide. Caffeine is sometimes effective and may be used in moderation. Propranolol is generally considered safe for migraine prophylaxis but may carry a risk for intrauterine growth retardation.

Other commonly used agents should be avoided. Ergotamines may cause birth defects secondary to vascular alteration. Triptans may cause vasospasm resulting in an increased incidence of preterm birth and intrauterine growth retardation. As is the case in other conditions, nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided.

**THROMBOEMBOLIC DISEASE**

Thromboembolic disease is a major source of maternal morbidity and mortality during pregnancy. The incidence of venous thromboembolism increases by a factor of 5 during pregnancy, and pulmonary embolism is a leading cause of maternal mortality in the United States. Factors believed to contribute to the increased incidence of venous thromboembolism include alteration of normal clotting factor levels, increased stasis, and vessel damage. These factors may be aggravated by advanced maternal age and inherited or acquired thrombophilias.

Ultrasoundography safely and reliably detects lower extremity deep vein thrombosis. If pelvic or iliac thrombosis is suspected, venography may be required for diagnosis, but magnetic resonance imaging is increasingly being used. Ventilation-perfusion scans are useful in assessing for pulmonary embolism; however, spiral computed tomography, available at most institutions, is associated with lower fetal radiation exposure than ventilation-perfusion scans are. Both heparin and low-molecular-weight heparin are commonly used for the treatment of acute thromboembolism. Warfarin is contraindicated in pregnant patients because of its association with fetal malformation and fetal demise.

**HYPERTENSION**

Pregnant women with elevated blood pressure may have pre-existing hypertension, gestational hypertension, preeclampsia, or eclampsia.

No consensus regarding initiation of antihypertensive therapy during pregnancy has currently been established.
Most authorities prescribe treatment for patients with a blood pressure of 160/105 or higher; others argue that a lower threshold of 150/100 should be the criteria for treatment. In one review of pregnant patients experiencing stroke secondary to preeclampsia, systolic blood pressures recorded before the event were 159 to 198 mm Hg, and diastolic blood pressures were 81 to 113 mm Hg; arterial hemorrhage was the cause of stroke in 93% of patients who underwent intracranial imaging. Of note, evidence is not sufficient to recommend bed rest as an effective or practical treatment of hypertension during pregnancy.24

**ALCOHOL AND OTHER RECREATIONAL DRUGS**

Alcohol use is reported in 10% to 15% of pregnancies; no safe level of intake has been determined. Alcohol abuse is associated with fetal alcohol syndrome. Common features of this syndrome include low IQ, microcephaly, small palpebral fissures, smooth filtrum, thin upper lip, and ventricular septal defects.

Cigarette smoking increases the risk for spontaneous abortion, prematurity, small-for-gestational-age births, placental abruption, placenta previa, and premature rupture of membranes. The adverse effects of smoking are dose related and reduced by cessation of smoking, even after a pregnancy is diagnosed.

Opiates, cocaine, and methamphetamine are all associated with obstetric complications. Cocaine use during pregnancy is believed to cause increased rates of placental abruption, preterm labor, and small-for-gestational-age infants. However, these studies are limited in that many of the mothers using cocaine have polysubstance abuse.

EPs should be aware of the reporting requirements of drug abuse in the states in which they practice.

**HUMAN IMMUNODEFICIENCY VIRUS AND ACQUIRED IMMUNODEFICIENCY SYNDROME**

Treatment of human immunodeficiency virus (HIV) infection during pregnancy with antivirals can reduce the incidence of perinatal transmission from mother to child by 85%. In the United States, where safe breast milk replacement is readily available, breastfeeding is discouraged because of the risk for transmission from mother to child. Referral to infectious disease and high-risk obstetric services is mandatory for pregnant women found to be HIV positive.

**MEDICATION USE DURING PREGNANCY**

Medication use during pregnancy can be a source of apprehension for both patients and physicians because of the paucity of data on safety. Pharmaceutical companies have excluded pregnant patients from testing of new agents for decades, thus resulting in little knowledge about the teratogenicity of products in humans. Additionally, animal models may not be representative of human risk. EPs prescribing medication for pregnant or lactating women should use the resources available in both electronic and text format.

Fetal toxicity is affected by the dose, duration of exposure, and gestational age when the exposure occurs. During the 31-day period following the last menstrual period, teratogens have essentially a binary (all-or-nothing) effect—the conceptus is either aborted or survives without harm. The next stage of development is the crucial period of organogenesis and lasts from 31 to 71 days after the last menstrual period. The effect of exposure to a teratogen depends on the time during this period that the fetus was exposed. Early exposure may affect the cardiovascular or central nervous systems (or both), whereas later exposure may affect the musculoskeletal system, such as palate and ears.

The U.S. Food and Drug Administration classifies medications into five categories according to potential fetal risk based on animal and human studies (Table 118.1).25 Medications commonly used in the ED and generally considered safe are listed in *Box 118.3*; often-used medications considered unsafe for use during pregnancy are listed in *Table 118.2*.

**ANALGESIC AGENTS**

No evidence has implicated acetaminophen as a teratogen, and thus it is the preferred agent when a mild analgesic or antipyretic is indicated. The use of NSAIDs such as ibuprofen and naproxen is generally discouraged during pregnancy, although the risk appears to be mostly in the third trimester. Indomethacin has been reported to be associated with oligohydramnios, pulmonary hypertension, and constriction of the ductus arteriosus.

Despite the lack of conclusive human data indicating that aspirin is a teratogen, its other ill effects limit its use during pregnancy. Aspirin has been linked to delayed onset of labor, protracted labor, and increased risk for prolonged pregnancy. It inhibits prostaglandin synthesis, which leads to premature closure of the ductus arteriosus, as well as increases the incidence of hemorrhage because of a decrease in platelet aggregation.

The use of opiates is considered safe throughout pregnancy. However, opiate use shortly before delivery can result in respiratory and central nervous system depression in the newborn. Because long-term opiate use during pregnancy can cause newborn addiction and withdrawal, patients using opiates chronically should be monitored carefully by their physician during pregnancy.

**ANTIEMETICS**

Multiple antiemetic agents are commonly prescribed during early pregnancy. Dopamine agonists such as the phenothiazines, promethazine, chlorpromazine, perphenazine, and metoclopramide are all well tolerated and appear to be safe in pregnancy. The serotonin 5-HT₃ receptor antagonist ondansetron also appears to be both safe and effective for nausea and vomiting during pregnancy, although fewer data are available about this agent. Vitamin B₆ has been reported to be an effective treatment of nausea and vomiting in several randomized, double-blind, placebo-controlled trials.

**ANTICOAGULANTS**

Warfarin is a known human teratogen associated with nasal bone hypoplasia, bone stippling, ophthalmologic abnormalities, and mental retardation; therefore, it is contraindicated in pregnancy. Heparin and low-molecular-weight heparin are thought to be safe during pregnancy and can be used when anticoagulation is indicated.
The macrolides (erythromycin, azithromycin, clarithromycin) are considered safe during pregnancy with the exception of erythromycin estolate, which is contraindicated because of the risk for maternal hepatotoxicity. Clindamycin and nitrofurantoin, both commonly used during pregnancy, are considered safe.

Metrodizole has not been shown to be a human teratogen. However, its use is somewhat controversial because of potential mutagenesis and carcinogenicity. Trimethoprim-sulfamethoxazole has two contraindications, one related to each of its constituents—trimethoprim should be avoided during the first trimester because it is a folate antagonist and its use may lead to an increased incidence of neural tube defects; use of sulfamethoxazole is discouraged near term because of competitive binding of albumin with bilirubin, which leads to concern for an increased risk for kernicterus. Although this concern exists for all sulfonamides, no cases of kernicterus resulting from prenatal use have been reported.27

Tetracyclines are contraindicated during pregnancy as a result of calcium binding, which causes staining of deciduous teeth, poor development of tooth enamel, and inhibition of skeletal growth in the fetus. Fluoroquinolones have not been shown to increase the rate of fetal malformation in humans but are contraindicated because of the development of arthropathy in immature animals exposed to quinolones.28,29

The aminoglycosides streptomycin and kanamycin are associated with ototoxicity and are potentially nephrotoxic. Gentamicin is potentially ototoxic and nephrotoxic; dosing must be adjusted for renal function, and it should be used with caution.

**ANTIVIRAL AGENTS**

Women with disseminated herpes infection or a first genital herpesvirus infection occurring during pregnancy should be treated with acyclovir. No cases of fetal abnormalities caused by acyclovir have been reported. A genital herpes outbreak at term necessitates cesarean delivery.

**ANTIEPILEPTIC DRUGS**

Management of epilepsy during pregnancy is difficult and requires a multidisciplinary approach. The risk for maternal death during pregnancy can be up to 10 times higher than that for patients without epilepsy.30 In addition, rates of intrauterine fetal demise and malformation are also increased.31 Many

ACE, Angiotensin-converting enzyme; CNS, central nervous system; NSAIDs, nonsteroidal antiinflammatory drugs.
commonly available anticonvulsant medications are known or suspected teratogens, which can make management decisions difficult for both caregivers and patients.

Phenytoin, carbamazepine, valproate, and lamotrigine are associated with an increased incidence of congenital abnormalities. A recent review of data from 25 epilepsy centers recorded the following rates of serious adverse outcomes: valproate, 20.3%; phenytoin, 10.7%; carbamazepine, 8.2%; and lamotrigine, 1.0%.32 Newer antiepileptic drugs, including levetiracetam, felbamate, gabapentin, oxcarbazepine, tiagabine, and topiramate, seem to be safe for use in pregnancy, although fewer data are available for these agents.33

Despite these risks, most physicians agree that patients with a well-established diagnosis of epilepsy should continue taking their medications during pregnancy. Women taking antiepileptic drugs during pregnancy should receive folic acid supplementation and undergo frequent monitoring. Seizures occurring during pregnancy or labor may be treated with benzodiazepines on an as-needed basis. Early studies demonstrated a risk for teratogenesis (mostly cleft abnormalities), but these findings have not been reproduced in more recent studies. Lorazepam does not cross the placenta at as fast a rate as other benzodiazepines do and, except during the first trimester, is considered safe. Sedation of the fetus around delivery is a minor concern and should not be considered a contraindication if needed for maternal seizures.

**ANTIHYPERTENSIVE MEDICATIONS**

Several agents for the treatment of hypertension during pregnancy have favorable safety profiles. Commonly used medications include α-methyldopa and hydralazine. Hydralazine has been used extensively in pregnancy and is available in both intravenous and oral formulations.34-36 Beta-blockers are believed to be safe in pregnancy, although some association with lower placental and fetal weight has been reported with atenolol.37 Labetalol is the preferred agent because it does not carry this risk. The combined alpha- and beta-blocking characteristics of labetalol may act to preserve uteroplacental blood flow.

Although fewer data are available on calcium channel blockers, they also appear to be safe and effective for use during pregnancy. Short-acting sublingual formulations of nifedipine should be avoided because they may cause maternal hypotension and fetal distress. Diuretics are safe but are not often used during pregnancy because preeclampsia may arise from a fluid-depleted state.

Two classes of antihypertensive agents, angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers, are contraindicated during pregnancy. Angiotensin-converting enzyme inhibitors have been associated with fetal renal malformation, oligohydramnios, craniofacial malformations, and lung malformations. Angiotensin II receptor blockers are associated with a similar set of malformations, probably caused by a similar mechanism.

**ANTIHYPERGLYCEMIC AGENTS**

Insulin is the primary medication for the treatment of diabetes during pregnancy and has been proven to be safe and effective. A regimen that includes multiple daily doses of both short- and long-acting insulin is often required. Data regarding the use of oral hypoglycemic agents in pregnancy are still limited. Glyburide and metformin have been used and appear to be safe, but there is little indication for initiating these agents in the ED setting. Patients are at increased risk for hypoglycemic episodes associated with oral hypoglycemic use and thus should be monitored closely.

**IMMUNIZATIONS**

Indications for vaccines composed of toxoid or inactivated virus are similar to those for nongravid females. In general, the protection gained by vaccination during pregnancy usually outweighs the risks.38 Live virus or attenuated vaccines (measles, mumps, poliomyelitis, rubella, yellow fever, and varicella) may cause infection or malformation (or both) in the fetus and are therefore contraindicated. Patients planning to become pregnant should ideally have their vaccines updated several months before conceiving.

Influenza is indicated for all women who will be pregnant during the flu season (October to March) and for all women at high risk for pulmonary complications.39 Tetanus–diphtheria toxoid vaccine should be administered as usual for tetanus-prone wounds.

**OVER-THE-COUNTER MEDICATIONS**

Most over-the-counter cold medications contain a combination of compounds. Little information is available regarding the effects of these agents alone and even less when they are used in combination. Decongestants act via vasoconstriction, and this mechanism also serves, at least theoretically, to decrease placental blood flow; their use during pregnancy should be avoided. Antihistamines such as diphenhydramine have been used during pregnancy and are considered safe. However, it should be noted that over-the-counter cold remedies are effective for relief of symptoms only and do not modify the course of disease; rest, hydration, and time are still the best treatment of the common cold.

REFERENCES

Approximately 25% of patients will experience some bleeding in the first trimester of pregnancy, with half of these patients proceeding to miscarriage. Risks for spontaneous abortion include advanced maternal age, previous spontaneous abortion, and prolonged time from ovulation to implantation. Other risk factors are smoking, alcohol, cocaine, caffeine, and use of nonsteroidal antiinflammatory drugs.

**PATHOPHYSIOLOGY**

The etiology of miscarriage can be classified as either intrinsic or extrinsic to the embryo. Intrinsic factors include genetic abnormalities and congenital conditions. Most cases of spontaneous abortion are due to genetic factors, either anembryonic gestations or chromosomal abnormalities. The majority of these defects arise de novo during fertilization and are not inherited. Genetic factors tend to lead to miscarriage early because of abnormal growth and development. In contrast, later miscarriage is more often a result of extrinsic factors.

Extrinsic causes of miscarriage include host factors such as such as fibroids, intrauterine adhesions, sepsis, maternal infections, hypercoagulable states, endocrine abnormalities, and teratogen exposure. Although blunt trauma to the abdomen is an unlikely cause of miscarriage because of the well-protected placement of the uterus in the pelvis, traumatic procedures such as chorionic villus sampling and amniocentesis may induce miscarriage.

**PRESENTING SIGNS AND SYMPTOMS**

Spontaneous abortion is classified as threatened, inevitable, incomplete, complete, missed, or septic. Table 119.1 lists characteristics of these categories. Symptoms of spontaneous abortion include vaginal bleeding, suprapubic cramping or pain, and passage of tissue. Bleeding can vary from minor spotting to severe hemorrhage.

Threatened abortion is defined by vaginal bleeding with or without mild suprapubic cramping or pain. It is the most common manifestation of spontaneous abortion seen in the emergency department (ED). Examination shows a closed cervix, uterine size that correlates to gestational age, and bleeding varying from scant to heavy. Ultrasound imaging confirms an intrauterine pregnancy and fetal heart tones in appropriate gestational ages. Threatened abortion may resolve with progression to normal pregnancy, or it may progress to other forms of miscarriage.
Before the 12th week of gestation, most spontaneous abortions will progress to completion with few complications. After this time, patients are more likely to have an incomplete abortion and require medical or operative intervention.

A septic abortion occurs when infection develops during any stage of the abortion process. Implicated agents include *Staphylococcus aureus*, gram-negative rods, gram-positive cocci, and anaerobes. Risk factors include elective abortion, miscarriage, spontaneous abortion, ectopic pregnancy, gestational trophoblastic disease, and bacterial vaginosis. Vaginal lacerations from intercourse or trauma may be to blame. Occasionally, nongynecologic sources such as rectal bleeding or hematuria are mistaken for vaginal bleeding.

### Differential Diagnosis and Medical Decision Making

As mentioned previously, bleeding in early pregnancy is common. It may represent benign bleeding from implantation or marginal separation of the placenta. Many cases are idiopathic. Pathologic processes in the differential diagnosis include ectopic pregnancy, gestational trophoblastic disease, cervicitis, subchorionic hemorrhage, and cervical or vaginal malignancy. Vaginal lacerations from intercourse or trauma may be to blame. Occasionally, nongynecologic sources such as rectal bleeding or hematuria are mistaken for vaginal bleeding.

Pregnancy should be confirmed by a positive urine HCG test. A speculum examination should be performed to assess the degree of bleeding and cervical dilation, as well as to inspect for expelled products of conception. Bimanual examination can assess uterine size, cervical opening, and any abnormal masses or tenderness.

Laboratory studies include a complete blood count, quantitative HCG, and blood type with Rh status. With significant bleeding or other medical disease, coagulation parameters and typing and crossmatching for blood products should be ordered. Ultrasonography is essential for a full diagnosis and for guiding further management (Fig. 119.1). Even if it appears that the patient has passed the embryo, she should undergo ultrasound imaging to evaluate for any retained products.

### Treatment

Many patients with spontaneous abortion often need little or no intervention following accurate diagnosis and exclusion of other pathology. Expectant management is the only option for threatened abortion; education and ensuring adequate follow-up care are essential. The presence of fetal heart tones in women with symptoms of threatened abortion is reassuring; less than 5% of women younger than 36 years will miscarry, but this risk rises to 29% in those older than 40.

Incomplete abortions may be managed either expectantly or by dilation and curettage. Both methods are generally acceptable. If products of conception are visible in the cervical os, gentle removal with ring forceps may allow the cervix to close and may control the bleeding. A complete abortion requires no further treatment as long as ultrasound scanning confirms that no retained products are present. Any retrieved tissue should be examined for villi, which will have a frondlike appearance.

Incomplete or missed abortions can be managed expectantly as long as shock, fever, or significant ongoing bleeding are absent. The time course for completion of a spontaneous abortion is highly variable, and patients will need education and routine gynecologic care to plan for dilation and curettage if tissue does not pass spontaneously or if the bleeding becomes heavy. Patients should attempt to collect the products of conception for examination and should undergo subsequent ultrasonography to assess whether all products of conception have passed. Studies have proved the safety of this practice.

Approximately 90% of patients with incomplete and 76% of those with missed abortions require no surgical treatment when managed expectantly for 4 weeks. Complications occur in 1%, less than in those managed medically.
Prostaglandins such as misoprostol can effectively induce abortion for pregnancy failure of longer than 12 weeks and may help control bleeding in patients with inevitable or incomplete abortions. The dose of misoprostol is 800 mcg administered vaginally or rectally, but this drug should be given only after consultation with a gynecologist. One large study showed an 84% success rate. Misoprostol induces spontaneous abortion, so any possibility of a desired viable pregnancy must be excluded.

Surgical management includes dilation and curettage or dilation and evacuation. Indications are listed in Box 119.1. Risks associated with surgical management are small and include uterine perforation, infection, adhesions, and anesthetic complications.

Women with significant hemorrhage or hemodynamic instability should first receive crystalloid volume replacement. If no response is seen or if the bleeding persists, either type-specific or type O-negative blood should be administered. Patients with septic abortions should be given broad-spectrum antibiotics in addition to dilation and curettage.

**Box 119.1 Indications for Dilation and Curettage in Patients with Spontaneous Abortion**

- Incomplete abortion
- Significant hemorrhage
- Signs of septic abortion
- Documented fetal demise or blighted ovum with no spontaneous passage (after a period of observation)
- Patient unwilling or unable to comply with expectant management

**RH₀ IMMUNE GLOBULIN**

Rh₀ immune globulin (Rh₀ IG) should be administered to any Rh-negative woman with signs of spontaneous abortion unless the father is also known to be Rh negative. It is administered in a dose of 50 mcg before the twelfth week of gestation and
in a dose of 300 mcg after 12 weeks. It is estimated that 50 mcg will neutralize 2.5 mL of fetal blood and that a 300-mcg dose will neutralize 15 mL. A 12-week-old fetus has approximately 4.8 mL of blood, and a 16-week-old fetus has about 30 mL of blood. It is unlikely that significant amounts of fetal blood will transfer to the maternal circulation during a first-term miscarriage, so the single, appropriate dose of immune globulin will be fully sufficient to prevent maternal antibody formation against the Rh antigen.

Rh₀ IG is effective for up to 12 weeks after administration, so patients with recurrent bleeding who already received immunization within that time frame do not need a repeated dose. If significant hemorrhage occurs later in pregnancy, especially in the setting of trauma, additional doses are necessary. Ideally, Rh₀ IG is administered within 72 hours of the event leading to fetal-maternal hemorrhage (Box 119.2).

Emergency gynecologic consultation is needed for patients with significant hemorrhage or signs of infection. Others may be managed expectantly or with close follow-up as long as adequate outpatient care is ensured. Patients with missed abortions may ultimately need surgical management if they do not spontaneously pass tissue.

Patients should be instructed to contact their physician or return to the ED if heavy bleeding, severe pain, or fever develops. Bleeding should resolve over the course of a few weeks, and menses will generally resume within 6 weeks. Pelvic rest (no vaginal intercourse, tampons, or douching) for 2 weeks is often recommended because of the theoretic risk for infection, although no studies support this risk. Patients are often advised to not become pregnant for 2 to 3 months, but again no studies show worse outcomes if another pregnancy is achieved during this interval.

Psychosocial issues surrounding miscarriage are common, including feelings of guilt and sadness. Reassuring women that most miscarriages are due to genetic abnormalities and are not the result of their actions is essential. Women with substance abuse leading to abortion should be counseled appropriately. Referral for grief counseling may be appropriate. Patients with recurrent miscarriages should be offered referral for fertility treatment and genetics counseling.

### ECTOPIC PREGNANCY

#### EPIDEMIOLOGY

Ectopic pregnancy, in which the developing embryo implants outside the uterine cavity, is responsible for the greatest morbidity and mortality in early pregnancy. The incidence of ectopic pregnancy in the United States has increased over the past 30 years, and it now accounts for 2% of all pregnancies. This increase has been attributed to rising rates of pelvic inflammatory disease, as well as the advent of assisted reproductive technologies.

At the same time there has been a decrease in the morbidity and mortality associated with ectopic pregnancy because of more widespread use of ultrasound and methotrexate. Despite advances in diagnosis and management, ruptured ectopic pregnancy remains responsible for 10% of pregnancy-related deaths.

#### PATHOPHYSIOLOGY

Risk factors for ectopic pregnancy are outlined in Box 119.3. Tubal pathology, the most significant risk factor, leads to abnormal transport and implantation of the embryo. The majority of cases arise in women with a history of pelvic inflammatory disease, and women with a previous ectopic pregnancy have a 15% recurrence rate. However, up to 50% of patients with an ectopic pregnancy have no identifiable risk factor.

Genetic abnormalities in the embryo have not been found to be a risk factor for abnormal implantation. Although women using an intrauterine device or those who have undergone a sterilization procedure are at decreased overall risk for pregnancy, the incidence of ectopic pregnancy is increased in those who do become pregnant. For example, the pregnancy rate after tubal ligation is 0.1% to 0.8%, but as many as one third of these pregnancies are ectopic.

The most common location for ectopic implantation is the fallopian tube, which accounts for 95% of all ectopic
Approximately one half of patients are asymptomatic before tubal rupture. Of those with rupture, 99% have abdominal pain, 74% have amenorrhea, and 56% have vaginal bleeding.

An interstitial, or cornual, pregnancy occurs when the embryo is implanted in the proximal portion of the tube that is embedded in the muscle of the uterus. The tube at this location is more distensible, so the embryo may grow undetected for a longer period. It may not be discovered until 12 weeks or later. Ultrasonography demonstrates an asymmetric uterine thickness surrounding the gestational sac. However, a skilled ultrasonographer is required, and in the early stages it may be mistaken for a normal intrauterine pregnancy. Cornual pregnancy is associated with a 2% to 2.5% maternal mortality rate and is more likely than other tubal pregnancies to require hysterectomy.

A heterotopic pregnancy occurs when an intrauterine pregnancy is present simultaneously with an ectopic gestation. Its incidence was at one time estimated to be 1 in 30,000, but the true incidence is unknown. Thus an ectopic gestation can essentially be excluded if an intrauterine pregnancy is demonstrated by ultrasonography. Patients using assisted reproductive techniques have up to a 1% incidence of ectopic pregnancy, highest in patients with transfer of multiple embryos. In these patients, an ectopic gestation should not be excluded solely on the basis of the presence of an intrauterine pregnancy.

The differential diagnosis of ectopic pregnancy is listed in Box 119.4. Because of the high potential for morbidity, any patient with abnormal vaginal bleeding or abdominal or pelvic pain should be considered to have an ectopic pregnancy until proved otherwise (see Fig. 119.1).

Quantitative Human Chorionic Gonadotropin Testing

Urinary HCG testing is essential for any woman of childbearing age with abdominal pain. Commercially available kits detect as low as 20 mIU/mL, although there have been case reports of ectopic pregnancy with an undetectable urine HCG.

| Differential Diagnosis and Medical Decision Making |

The differential diagnosis of ectopic pregnancy is listed in Box 119.4. Because of the high potential for morbidity, any patient with abnormal vaginal bleeding or abdominal or pelvic pain should be considered to have an ectopic pregnancy until proved otherwise (see Fig. 119.1).

Quantitative Human Chorionic Gonadotropin Testing

Urinary HCG testing is essential for any woman of childbearing age with abdominal pain. Commercially available kits detect as low as 20 mIU/mL, although there have been case reports of ectopic pregnancy with an undetectable urine HCG.
level.\(^{10}\) If high clinical suspicion still exists despite negative urinary HCG, a serum HCG test should be ordered.

In normal pregnancy, HCG production begins shortly after fertilization with a peak of about 100,000 mIU/mL at approximately 41 days' gestational age. In the early weeks of normal pregnancy, HCG levels are expected to double roughly every 48 hours, with a range of 1.4 to 2.1 days. In contrast, HCG levels generally rise more slowly with ectopic and nonviable intrauterine pregnancies. However, in some normal pregnancies, HCG levels may increase as little as 66% over a 48-hour period,\(^{11}\) and up to 17% of ectopic pregnancies have normal doubling times. Patients should have serial measurements done by the same laboratory because interassay variability may be as high as 15%.

**ULTRASONOGRAPHY**

Transvaginal ultrasonography is essential for making the diagnosis. A visible extraterine gestational sac with a yolk sac or embryo confirms the diagnosis of ectopic pregnancy, but this is seen in less than half of cases. Highly suggestive findings include a complex adnexal mass or free fluid in the pelvis in conjunction with an empty uterus.

**Ultrasoundographic Findings Plus Human Chorionic Gonadotropin**

To obtain the full benefit of transvaginal ultrasonography, serum HCG levels must be taken into consideration.

The earliest ultrasonographic confirmation of intrauterine pregnancy is a true gestational sac seen within the uterine cavity. The sac is routinely visualized when HCG levels reach 1500 to 2000 mIU/mL, but it can be detected with levels as low as 800 mIU/mL. The discriminatory zone refers to the level of HCG at which a true gestational sac can be seen. Lack of an intrauterine pregnancy with an HCG level above the discriminatory zone raises concern for ectopic pregnancy or a failed intrauterine gestation. The discriminatory zone is generally accepted to be in the range of 1500 mIU/mL but is dependent on equipment quality and operator skill.

Transvaginal sonograms are more likely to be nondiagnostic in women with very low HCG levels, but they may still be useful. Given its safety, transvaginal ultrasonography should be performed on all women with a suspected ectopic pregnancy, even those with HCG levels below the discriminatory zone.\(^{12}\) In a study by Kaplan et al., 19% of patients with HCG levels higher than 1000 mIU/mL at the time of evaluation had transvaginal sonograms diagnostic of an ectopic pregnancy.\(^{12}\)

The specificity of the ultrasonography findings was 100%.

As discussed previously, ectopic pregnancy is visualized by ultrasonography only half of the time; therefore, women with serum HCG levels below the discriminatory zone and nondiagnostic ultrasonographic findings present a clinical challenge. These findings may represent an ectopic pregnancy or a nonviable early intrauterine pregnancy. In these cases, HCG testing and ultrasonography should be repeated at 48 to 72 hours. HCG levels increasing normally at 48 to 72 hours should be monitored until the intrauterine pregnancy can be seen on the sonogram. A decreasing HCG level is most consistent with a failed pregnancy or spontaneously resolving ectopic pregnancy. In these cases, serial measurements should be monitored until HCG reaches nondetectable levels.

Patients with HCG levels that plateau or rise by less than double in 72 hours are likely to have either a nonviable intrauterine or an ectopic pregnancy. Repeated transvaginal ultrasonography may be helpful to distinguish the two. Failure to visualize an intrauterine gestation with HCG levels higher than 2000 mIU/mL excludes the possibility of a viable pregnancy. These patients have a high likelihood of having an ectopic gestation and should be treated accordingly.\(^{13}\)

Patients with HCG levels higher than 1500 mIU/mL may undergo dilation and curettage to obtain tissue for examination. Confirmation of villi in the curettage specimen confirms the diagnosis of a failed intrauterine pregnancy, whereas their absence suggests an ectopic pregnancy. Laparoscopy may then be used to provide a definitive diagnosis and guide treatment.

**TREATMENT**

Ruptured ectopic pregnancy may have dramatic findings, with the patient in hemorrhagic shock. Rapid stabilization with intravenous fluids and packed red blood cells is essential. Unstable patients may require O-negative blood until a full crossmatch is performed. Laboratory studies include a complete blood count, quantitative HCG, and coagulation studies. The gynecology department should be consulted for operative management. Rh-negative patients should receive Rh0 IG.

In stable patients, treatment of confirmed unruptured ectopic pregnancy may be medical, surgical, or expectant.

**METHOTREXATE THERAPY**

The medical treatment of choice is methotrexate, a folate antagonist that inhibits DNA synthesis in rapidly dividing cells such as embryonic tissue. This action leads to medically induced abortion of the embryo. Despite limitations, use of methotrexate allows noninvasive management and has proved successful in properly selected patients. Methotrexate protocols vary by institution, but single-dose treatment consisting of an intramuscular injection of 50 mg/m\(^2\) of body surface area is widely used.

The ideal candidate for methotrexate therapy is relatively asymptomatic with no significant pain or bleeding. A minority of patients will fail treatment or progress to rupture, and the patient must be made aware of these possibilities. Criteria predicting success include diameter less than 3.5 cm, absence of cardiac activity on ultrasonography, and HCG level lower than 5000 mIU/mL. Patients with lower HCG levels tend to have fewer treatment failures.\(^{14}\)

Patients should be counseled on the risks and benefits of methotrexate therapy. They must be willing to comply with follow-up visits and have ready access to care. The patient should be aware of the possibility of treatment failure.

Relative contraindications include a high HCG level (>6000 mIU/mL), visible cardiac activity, and a large ectopic mass. Although visible cardiac activity is generally considered a contraindication, one study showed good results despite this finding.\(^{15}\) Absolute contraindications to the use of methotrexate include hemodynamic instability, as well as the factors listed in Box 119.5.

Side effects of methotrexate include stomatitis, conjunctivitis, enteritis, pleuritis, bone marrow suppression, and elevated liver function test results. Thirty percent of patients are affected, but most symptoms are mild and self-limited. The
majority of patients will experience some abdominal pain, usually 2 to 3 days after methotrexate administration, because of tubal abortion with subsequent hematoma formation. In contrast to the pain from rupture, this pain is milder, and patients do not have hemodynamic instability or signs of a surgical abdomen. Although only 20% of patients with abdominal pain following methotrexate administration will ultimately need laparoscopy to evaluate for rupture, this subset can be difficult to identify. Transvaginal ultrasonography should be performed in these patients to evaluate for rupture.\textsuperscript{16}

It is normal for HCG levels to increase for as long as 4 days following methotrexate administration. Patients typically have HCG testing repeated between days 4 and 7. By day 7, if the serum HCG level has not decreased by 25%, a second dose of methotrexate is given (required in 15% to 20% of patients), and HCG values are monitored weekly until levels decrease to less than 10 to 15 mIU/mL. Success rates with methotrexate range from 86% to 94%.

Surgical treatment is the only option for unstable patients with ectopic pregnancy. It is also indicated for patients with large ectopic masses, patients unable or unwilling to comply with the monitoring associated with methotrexate therapy, and patients with poor access to emergency care.

Resection of the ectopic mass with preservation of normal anatomy is ideal. Consequently, salpingostomy is preferred over salpingectomy. Laparoscopic resection is the standard approach, although laparotomy is occasionally required. After surgery, patients should be monitored with weekly HCG testing given the slight possibility of persistent ectopic tissue following resection.

A recent review showed the highest success rates with salpingostomy, although single-dose methotrexate therapy had the lowest financial cost and the least impact on quality of life.\textsuperscript{17} Methotrexate therapy was less costly in patients with HCG levels lower than 1500 mIU/mL. The cost of medical therapy increases in patients with higher HCG levels because of the increased risk for failure, the requirement for multiple doses, and the need for extended monitoring.

Stable patients with nondiagnostic HCG and ultrasound findings are designated as having a pregnancy of unknown location. Expectant management relies on the fact that the spontaneous resolution rate of pregnancies of unknown location is 70%.\textsuperscript{18} These patients are monitored with serial HCG levels and ultrasonography until a definitive diagnosis can be made. Expectant management is most successful in patients with HCG levels lower than 200 mIU/mL; increased complications occur in those with HCG levels higher than 1500 mIU/mL. However, the complication of tubal rupture can develop in as many as 30%, and it may occur even with decreasing HCG levels, so patients must be aware that treatment failures do occur.

In consultation with the patient’s gynecologist, patients with a confirmed ectopic pregnancy should receive methotrexate or be transferred for operative management. Low-risk patients with an indeterminate work-up who are clinically stable may be discharged with appropriate follow-up in 48 to 72 hours for repeated HCG testing and ultrasonography. Patients without access to follow-up may be admitted for observation. Patients with a pregnancy of unknown location should be counseled about the possibility of an ectopic pregnancy.
Gestational Trophoblastic Disease

Epidemiology

The incidence of gestational trophoblastic disease (GTD) varies from 1 per 1000 pregnancies in the United States to 2 per 1000 pregnancies in Japan. Well-established risk factors include nulliparity, personal history of GTD, and maternal age younger than 20 or older than 35 years. Heavy smoking, oral contraceptive use, infertility, and maternal blood types AB or B are also risk factors. Although the disease carried significant morbidity in the past, earlier diagnosis with ultrasonography and more sensitive HCG measurements have led to more successful treatment in recent years.

Pathophysicsiology

GTD is a disorder of abnormal proliferation of trophoblastic tissue. The benign form is a hydatidiform mole, whereas the malignant forms are grouped as gestational trophoblastic neoplasia, which includes choriocarcinoma, placental site trophoblastic tumor, and persistent or invasive GTD. Although GTD is classically associated with molar pregnancy, it may result from any gestational event, such as spontaneous abortion or term pregnancy.

The most common form of GTD is a hydatidiform mole, either partial or complete. A partial mole contains fetal tissue and arises from fertilization of a haploid ovum by two sperm or by a single sperm that then duplicates. In contrast, a complete mole has no fetal tissue or maternal DNA and results from fertilization of an enucleate egg. Up to 15% of complete moles result in malignancy, whereas malignant transformation of a partial mole is less common. Table 119.2 lists the typical characteristics of molar pregnancies.

The abnormal trophoblastic tissue in GTD secretes HCG, thereby resulting in quantitative serum levels much higher than predicted in normal pregnancy. Patients with GTD have an increased incidence of hyperemesis gravidarum and early preeclampsia. Hyperthyroidism may result because of the structural similarity of HCG and thyroid-stimulating hormone. Theca lutein cysts seen in patients with GTD are bilateral, multiloculated ovarian cysts that are present in 15% to 25% of patients with complete moles.

Trophoblastic hyperplasia causes uterine enlargement abnormal for the stage of pregnancy. Deeper uterine invasion may result and lead to severe hemorrhage from destruction of the myometrium or uterine vasculature. Malignant forms of GTD may spread into the pelvis or be manifested as distant metastases, most commonly to the liver, lungs, vagina, and brain.

Presenting Signs and Symptoms

The most common complaint with molar pregnancy is first trimester vaginal bleeding. Patients may also complain of pelvic pain or pressure, and there may be passage of hydropic vesicles from the vagina.

Complete moles have a more striking clinical manifestation, with uterine size larger than expected at the stage of pregnancy, absent fetal heart tones, and markedly elevated HCG levels. Vaginal bleeding may be heavy. Medical complications include pregnancy-induced hypertension, early preeclampsia, hyperthyroidism, anemia, and hyperemesis gravidarum.

In contrast, the manifestation of a partial mole is subtle. Symptoms are similar to those of spontaneous abortion, with mild to moderate bleeding and cramping. Patients typically do not have significant uterine enlargement, and the diagnosis is made only when the abnormal placental tissue is visualized on ultrasonography. Patients with partial moles are less likely
to have the medical complications associated with complete moles because HCG levels are lower. As mentioned earlier, GTD may also develop after a nonmolar pregnancy, such as spontaneous and elective abortion, ectopic pregnancy, and term gestation. These patients have prolonged bleeding after delivery or miscarriage, with subsequent HCG levels that fail to return to undetectable measurements. Up to 75% of cases of malignant GTD occur after nonmolar pregnancies. Because placental site trophoblastic tumors may occur years after pregnancy, GTD should be considered in a woman with metastatic disease from an unknown primary site.21

**Differential Diagnosis and Medical Decision Making**

Molar pregnancy should be included in the differential diagnosis of any patient with first trimester bleeding (see Box 119.4). Abnormally elevated quantitative HCG levels suggest the diagnosis, although there is no absolute level that identifies molar pregnancy. Pelvic ultrasonography is diagnostic in almost all cases. Tissue obtained from uterine evacuation provides histologic confirmation.

Ultrasonographic findings in a patient with a complete mole include diffuse hydatidiform swelling of chorionic villi (“snowstorm pattern”), bilateral theca lutein cysts, and absence of fetal tissue or amniotic fluid. The ultrasonographic appearance of a partial mole is not as striking and may be misinterpreted by an inexperienced ultrasonographer. There is only focal hydatidiform swelling with absence of theca lutein cysts. Growth-restricted embryonic tissue or amniotic fluid may also be seen.

Laboratory tests should include a complete blood count, blood typing and antibody screen, clotting function analysis, renal and liver studies, and measurement of the serum HCG level. For patients with malignant disease, additional work-up includes chest radiography to search for metastases. Other appropriate studies include computed tomography of the chest and magnetic resonance imaging of the abdomen, pelvis, and brain.

**TIPS AND TRICKS**

**Gestational Trophoblastic Disease**

Molar pregnancy should be in the differential diagnosis of patients with exaggerated symptoms of pregnancy such as hyperemesis and early preeclampsia. In patients with spontaneous abortion, the products of conception should be sent for pathologic evaluation because of the possibility of incidental molar pregnancy. The clinician should consider gestational trophoblastic disease in patients with prolonged or abnormal bleeding after delivery or miscarriage.

**TREATMENT**

GTD is likely to be diagnosed only incidentally in the ED during evaluation for spontaneous abortion or ectopic pregnancy. Most patients have few or mild symptoms. Initial ED management includes supportive care for significant hemorrhage, including intravenous fluids and blood products. Rh0 IG should be administered to Rh-negative women. Patients with rupture or torsion of theca lutein cysts may require operative management, although rupture is rare.22

**Next Steps in Care and Follow-Up**

Any woman with suspected or diagnosed GTD should be referred to a gynecologic oncologist urgently because the disease may progress quickly. Definitive management of molar pregnancy includes dilation and curettage. As long as serial HCG levels decline appropriately, no further treatment is needed. Persistent local disease is usually treated with chemotherapy, although hysterectomy may be performed in women with locally invasive disease who no longer desire fertility.

Posttreatment monitoring for malignant or persistent disease consists of serial HCG measurements. Patients should have frequent pelvic examinations to monitor for local recurrence or vaginal metastases. Patients should be instructed to use contraceptive methods for 12 months because an increase in HCG levels as a result of pregnancy would obscure the monitoring results. Affected patients have an approximately 1% chance for a recurrent mole in future pregnancies, although this risk increases to as high as 28% after two molar pregnancies.21

**Hyperemesis Gravidarum**

**Epidemiology**

Estimates of the incidence of hyperemesis gravidarum range from 0.3% to 2% of all pregnancies. Risk factors include multiple gestations, GTD, personal or family history of hyperemesis, and female sex of the fetus. Protective factors include advanced maternal age, cigarette smoking, and anosmia. Hyperemesis gravidum is responsible for the highest percentage of hospital admissions during the first half of pregnancy.24,25

**Pathophysiology**

Up to 85% of pregnant patients experience nausea and vomiting to some degree. Hyperemesis gravidarum has no strict diagnostic criteria, but it is generally defined as nausea and vomiting that results in loss of 5% or more of prepregnancy weight, as well as ketonuria. In addition, the symptoms must not be attributable to another medical condition. Hormonal factors are believed to be the pathogenesis. Studies have shown that women with higher HCG and estradiol concentrations have an increased incidence of hyperemesis, but the mechanism is unknown.26 In contrast, no correlation of progesterone levels and symptoms has been shown. Other potential causes such as vitamin deficiencies, gastric motility, and Helicobacter pylori infection have not been consistently
linked to the disease. The belief in the past that psychologic issues were causative has no supporting data.

### PRESENTING SIGNS AND SYMPTOMS

Hyperemesis classically begins early in the first trimester, with symptoms peaking at 9 to 10 weeks and generally resolving by 16 to 18 weeks. Most patients report more severe symptoms in the morning hours, often made worse by noxious smells. Frequently, multiple ED visits or interactions with a primary care provider occur because of the persistence of symptoms.

Symptoms of abdominal pain and tenderness are usually minimal; such findings suggest another pathology. The physical examination confirms varying levels of dehydration.

Complications include dehydration, weight loss, and vitamin deficiencies. Esophagitis, Mallory-Weiss tears, and Wernicke encephalopathy have been reported in patients with persistent vomiting and malnutrition. Anxiety, as well as depressive symptoms, may occur in response to the illness.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The diagnosis of hyperemesis gravidarum is one of exclusion given the lack of confirmatory testing available. A careful history should confirm that the symptoms began in the first trimester, with review of systems negative for symptoms consistent with coexistent pathology. Physical examination is aimed at identifying these other conditions. **Box 119.6** outlines the differential diagnosis of hyperemesis.

Serum HCG measurements and ultrasonography can determine the time of gestation and rule out a hydatidiform mole. Urinalysis can rule out infection and may reveal ketonuria and high specific gravity. Laboratory evaluation can be helpful in excluding other pathology. Initial testing includes a complete blood count; basic chemistry panel; and liver, amylase, lipase, and thyroid function assays, including thyroid-stimulating hormone and free thyroxin levels.

As many as half of patients with hyperemesis will have mild elevations in transaminases; levels are usually in the low hundreds, with alanine transaminase levels being higher than aspartate transaminase levels. Amylase and lipase may be elevated, but much less so than with pancreatitis. Typical laboratory test results include hemoconcentration, electrolyte abnormalities, and mildly elevated hepatic and pancreatic function via urinalysis. The laboratory test abnormalities generally resolve by the 20th week of gestation, and no treatment is necessary.

### TREATMENT

After coexistent pathology has been ruled out, treatment consists of rehydration, correction of electrolyte abnormalities, control of nausea, and reinstatement of nutrition. Volume resuscitation is accomplished with normal saline or lactated Ringer solution. Dextrose-containing solutions can then be used for maintenance fluids. Potassium, magnesium, and phosphorus supplements should be added to fluids as needed. Patients with prolonged vomiting should be given thiamine (100 mg/day) and multivitamins intravenously.

Pharmacotherapy is appropriate significant nausea, although patients may have reservations about using these medications. The combination of pyridoxine (10 mg) and doxylamine (12.5 mg) three to four times a day is considered safe; randomized, placebo-controlled studies have shown a 70% reduction in nausea and vomiting. This combination should be considered first-line therapy.

Various antiemetics (**Table 119.3**) have been used for hyperemesis with good results and reasonable safety data. Antihistamines have the best safety profile, but phenothiazines, metoclopramide, and ondansetron are considered safe as well. Gynecologists may prescribe oral corticosteroids for patients with refractory nausea and vomiting. Studies have shown conflicting results of effectiveness, and the incidence of cleft palate appears to be slightly increased in infants whose mothers received methylprednisolone in the first trimester of pregnancy. Steroids should thus be reserved as a last resort.

| **Table 119.3** Antiemetics for Hyperemesis Gravidarum |
|--------------------------- |---------- |--------- |
| MEDICATION        | SAFETY CLASSIFICATION | DOSAGE |
| Doxylamine     | A         | 12.5 mg PO |
| Dimenhydrinate | B         | 50-100 mg PO, PR; 50 mg IV |
| Metoclopramide | B         | 5-10 mg PO, IV, IM |
| Ondansetron    | B         | 4-8 mg PO, IV, IM |
| Promethazine   | C         | 12.5-25 mg IV, IM, PO, PR |
| Prochlorperazine| C         | 5-10 mg IV, IM, PO; 25 mg PR |

**IM**, Intramuscularly; **IV**, Intravenously; **PO**, orally; **PR**, parenterally.
Many patients are reluctant to use pharmacotherapy because of a perceived fear of birth defects. These patients may be agreeable to adjunctive therapies such as acupuncture, hypnosis, and powdered ginger. Studies of acupuncture and acupressure have yielded conflicting results, whereas hypnosis has been shown to decrease vomiting in patients with hyperemesis. Powdered ginger (250 mg to 1 g/day) is as effective as pyridoxine, but its safety is not well established.

The ultimate goal of treatment is restoration of nutrition. Many patients are able to tolerate feeding after a short course of rehydration along with gut rest. The Patient Teaching Tips box outlines dietary suggestions.

Patients who cannot maintain their weight despite rehydration and antiemetics are candidates for enteral nutrition. Those who cannot tolerate enteral feedings should be given total parenteral nutrition. This regimen carries the usual risks of infectious and metabolic complications.

PATIENT TEACHING TIPS

Hyperemesis
Daily multivitamin use at the time of conception may decrease the severity of nausea and vomiting.
Avoid triggers such as noxious odors, brushing teeth after eating, and iron supplements.
Eat small, frequent meals rich in protein and carbohydrates and low in fat. Avoid spicy foods.
Eat as soon as you feel hungry.
Drink small amounts of liquids often. Cold, clear, carbonated, and sour liquids are best tolerated.
Aromatic mint tea and teas with lemon or orange flavoring may be helpful.

NEXT STEPS IN CARE AND FOLLOW-UP

Patients with mild dehydration may be discharged home after fluid and electrolyte repletion. Antiemetics can be prescribed for home use after appropriate discussion with the patient and primary physician. Many patients come to the ED before they have established prenatal care; ensuring adequate outpatient care is essential. Patients with severe dehydration, significant electrolyte abnormalities, progressive weight loss, and intractable vomiting despite antiemetics should be admitted to the hospital.

Patients should be instructed to return to the ED if vomiting persists or if they experience new symptoms such as abdominal pain and fever. Patients with only mild nausea and vomiting are not at increased risk for low-birth-weight infants or birth defects. Although patients with true hyperemesis do have a higher incidence of low-birth-weight infants, appropriate weight gain later in pregnancy reduces this risk.

**INTRODUCTION**

All female patients of reproductive age seen in the emergency department (ED) with vaginal bleeding or abdominal or back pain should have a urine or serum pregnancy test performed. Ectopic pregnancy is the number one cause of death in patients in the first trimester. Emergency physicians (EPs) caring for these patients understand that no historical clues or physical findings can effectively affirm or refute an ectopic pregnancy. Ultrasound is the initial imaging modality of choice to locate a pregnancy in the first trimester. Emergency physicians proficient in ultrasound are capable of rapidly diagnosing ectopic pregnancy and expediting definitive care. Most first trimester pregnancies can be localized within the uterus on initial ultrasound in the emergency department. All patients discharged from the emergency department without a confirmed intrauterine pregnancy by ultrasound should thoroughly understand the "ectopic precautions," have close outpatient follow-up arranged with their obstetrician, and have the means to return immediately to the emergency department if complications arise.

**EVIDENCE-BASED REVIEW**

In most EDs, when “formal” ultrasound is traditionally ordered, it is actually performed in the department of radiology. This requires (1) time to transport the patient out of the ED, (2) a sonographer available to obtain the images, and (3) a radiologist to interpret the study. Ultimately, the combination of these factors postpones the diagnosis, delays definitive care, and increase the patient’s length of stay. As an alternative to formal ultrasound, many EPs have learned how to perform and interpret ultrasound images at the patient’s bedside. As early as 1989, a number of small studies suggested that EPs were able to perform ultrasound for ectopic pregnancies with high sensitivity. When previous studies from multiple institutions are compiled to increase the sample size ($N = 2057$), it is estimated that EPs have a pooled sensitivity of 99.3% when diagnosing ectopic pregnancies at the bedside. Sensitivity is defined as the proportion of bedside ultrasound images demonstrating a true absence of definitive intrauterine pregnancy (IUP) in patients with ectopic pregnancies.

Multiple retrospective and prospective studies from the late 1990s and early 2000s have reported that when compared with formal imaging, the use of bedside ultrasound to evaluate first trimester bleeding reduced length of stay in the ED by a mean time of 48 to 169 minutes. Time of day, day of the week, and whether ultrasound technicians were in house 24 hours a day were some of the factors that had an impact on the length of stay. In some cases this was a 40% savings in billed charges. Literature from the past 20 years has and continues to demonstrate that ultrasound performed by an EP to evaluate for ectopic pregnancies is feasible, fast, and accurate. Bedside ultrasound in symptomatic first trimester pregnant patients has high sensitivity in ruling out ectopic pregnancy, speeds time to diagnosis, and decreases true costs.

**HOW TO SCAN**

The pelvic organs may be evaluated with one of two different sonographic methods of interrogation: the transabdominal or the endovaginal technique. In the transabdominal approach,
the probe is positioned over the lower portion of the abdomen, just superior to the pubic symphysis, and directed inferiorly into the pelvis because the uterus typically remains a pelvic organ until approximately the 12th week of pregnancy. In the endovaginal approach, the probe is inserted into the vaginal vault, directly in touch with the cervix. These “windows” into the pelvis are illustrated and discussed in the following sections.

**TRANSABDOMINAL TECHNIQUE**

The transabdominal technique has long been used to evaluate first trimester pregnant patients and is best done with a curvilinear probe. Before the ultrasound examination, a Foley catheter can be inserted to fill the bladder. The practice of filling the bladder accomplishes two things. First, a full bladder displaces bowel out of the anterior cul-de-sac and acts as an acoustic window to the pelvic organs. Second, a full bladder generally aligns the uterus such that its long axis parallels the abdominal wall. This allows the transmitted sound waves to strike the uterus at a nearly perpendicular angle, which produces better reflections when the returning echoes are received by the transducer and plotted on the monitor. Although this optimizes image quality, adequate images can often be achieved without this maneuver.

In the sagittal view, in which the uterus is seen in its long axis, the probe is placed just superior to the pubic symphysis with the indicator pointed toward the patient’s head. The anterior-most organ on screen is the fluid-filled, triangular-shaped bladder. Just posterior to the bladder is the pear-shaped uterus. The uterus more commonly lies in an anteverted position, with the fundus pointed toward the anterior abdominal wall, but it may also be seen in a retroverted lie with the fundus pointing posteriorly toward the spine. The endometrial stripe serves as the landmark for identifying the longitudinal uterus in the midline. The endometrial stripe is a result of the endometrial mucosal lining coming together to form a hyperechoic, curvilinear line that continues as the cervical stripe more inferiorly (Fig. 120.1, A and B). After the midline of the longitudinal uterus is identified, the probe is panned from side to side to evaluate the entire width of the uterus. Much of the hyperechoic area surrounding the uterus is the bowel and rectum, which are poorly defined because of their solid and gas contents.

In the transverse view, the probe is rotated 90 degrees counterclockwise so that the indicator is pointed toward the patient’s right. With the probe angled inferiorly to visualize into the pelvis, the anterior-most organ is the fluid-filled, rectangular-shaped bladder. Posterior to the bladder is an ovular-shaped cut of the uterus in the transverse view with the hyperechoic endometrial stripe in the center. The rectum and bowel are hyperechoic areas surrounding the bladder and uterus posteriorly and laterally. The uterus should be evaluated from the top of the fundus inferiorly through to the cervix. Though not always visualized, the ovaries may be seen lateral to the fundus of the uterus in either the sagittal or transverse view.

Advantages of the transabdominal technique include (1) an overall view of the true pelvis and (2) a faster examination. The lower-frequency curvilinear probe will penetrate deeper into the pelvis, and although the images might be a little fuzzy, a “full” view of the pelvis is provided. Second, in patients who are farther along in the first trimester or whose bladder is not completely empty, adequate transabdominal views can be obtained without filling the bladder. Less preparation time is needed to scan these patients, and enlisting the assistance of a coworker to chaperone is unnecessary.

The main disadvantage of the transabdominal technique results from the use of a lower-frequency probe. The lower frequency (2- to 5-MHz curvilinear probe) means less resolution and thus the pregnancy must be farther along (usually 7 to 8 weeks’ gestational age) to be visualized. The transvaginal probe is a higher-frequency probe (5 to 9 MHz) with increased resolution, which means that pregnancies as early as 5 to 6 weeks can be visualized.

**ENDOVAGINAL TECHNIQUE**

The arrival of endovaginal transducers in the 1980s significantly improved the quality of ultrasound imaging in female patients. Simplified, the engineering design placed an ultrasound transducer on the end of a stick that could be inserted into the vaginal vault, directly in touch with the cervix. These “windows” into the pelvis are illustrated and discussed in the following sections.

**Fig. 120.1**  A and B, Transabdominal views of the sagittal plane of the uterus revealing the typical landmarks of the uterus, endometrial stripe, cervix, bladder, and vaginal stripe.
into the vaginal vault. This permits the transducer scanning head to be in close proximity to the pelvic organs, which has several important implications in ultrasound imaging. First, there is a clearer path to transmit and receive echoes, and second, the shorter distance between the transducer and the pelvic organs allows higher transducer frequencies to be used. In contrast to the transabdominal approach, the quality of images from an endovaginal approach is enhanced with an empty bladder because of less distortion of the pelvic anatomy.

The high-frequency endocavitary probe is prepared by directly placing ultrasound gel on the transducer head, sheathing the probe with a sterile cover, and then adding more sterile gel over the sheathed transducer head. If it is not possible to place the patient in the lithotomy position on a gynecology examination table, it is important to adequately prop up the patient’s pelvis for any modified positioning. It is often necessary to manipulate the handle of the probe below the level of the pelvis for better visualization. The covered probe is then inserted into the vaginal vault to begin scanning. Some patients and practitioners have found it more comfortable for patients to insert the probe.

For the sagittal view, the transducer is inserted so that the indicator is straight up and down, with the body sliced into left and right halves. Even after voiding, the bladder usually retains a small amount of fluid, which enables this anechoic structure to be used as a landmark in endovaginal imaging. After initially placing the probe into the vaginal vault, the bladder or uterus (or both) may not initially be visible. To look for these structures, the handle of the probe should be brought down and the footprint of the probe tilted more anteriorly and angled up to get the uterus in its full, longitudinal (sagittal) plane. In this plane, the anterior-most structure is a sliver of bladder, the pear-shaped uterus is posterior to the bladder, and the more hypoechoic bowel and rectum surround the uterus (Fig. 120.2, A to C). As in transabdominal imaging, the endometrial stripe serves as the landmark for identifying the longitudinal uterus in its midline. Once it is identified, the uterus should be interrogated along its entire width by fanning from side to side.

For the coronal view the probe is rotated 90 degrees counterclockwise, with the body cut into anterior and posterior components. As in the sagittal view, the probe is tilted anteriorly by moving the handle of the probe downward to obtain transverse cuts of the uterus. Depending on the depth of probe insertion, some part of the bladder may be seen. Deep to the bladder lies the oval uterus, which is surrounded by the rectum and bowel.

Advantages of the endovaginal technique include (1) superior resolution and (2) a wider field of view. The shorter pathway from the transducer to the pelvic structures permits the use of higher frequencies. Sound attenuation is limited, and waves reflected from nearby objects are maximized. These higher-frequency probes, with their inherent enhanced resolution, provide the EP with more clinical confidence when interpreting images. In addition, most endovaginal transducers incorporate a beam angle that provides a 120- to 180-degree field of view.

Disadvantages of the endovaginal technique include (1) increased invasiveness, (2) more time to prepare and perform the scan, and (3) decreased depth of view. As the endovaginal probe is inserted into vaginal vault, there is a small risk of transmitting disease through an improperly sanitized probe. Second, the taboo of having an unknown physician insert a probe into the vaginal vault may require greater explanation of the procedure. Optimal examination is performed with a gynecology table, which may be a limited resource. More time commitment is involved in preparation for the endovaginal study and obtaining a chaperone. Third, the higher-frequency probes used for endovaginal scanning limit the range of the transmitted echo. Generally, a full view of the pelvis is not achieved with transvaginal scanning.

### IDENTIFICATION AND LOCALIZATION OF THE PREGNANCY

First trimester pregnancies can be categorized into three groups according to location: intrauterine, extraterine, or indeterminate (Box 120.1). Within these three categories, further subdivisions into one of five diagnostic possibilities based on specific criteria (Box 120.2) are possible. The significance of this unambiguous classification scheme is that it corresponds with EP management strategies for first trimester symptomatic patients.

### INTRAUTERINE PREGNANCY

To define a pregnancy as intrauterine, it is imperative to have a clear understanding of the criteria necessary to support the
diagnosis by ultrasound (Box 120.3). The first component of the criteria is to visualize a gestational sac with a mean sac diameter (height, width, and length) larger than 5 mm and an echogenic ring. Second, this gestational sac must be clearly visualized within the endometrial lining of the uterus and many times may demonstrate a “double decidual sac sign.” Finally, this gestational sac, which lies within the endometrial echo of the uterus, must contain a yolk sac or a fetal pole. Although this may be excessive for a radiologist who uses the double decidual sac sign as the earliest criteria for an IUP, it is a conservative safety measure that has served EPs well to avoid confusing the pseudogestational sac of an ectopic pregnancy with a true IUP. Because ectopic pregnancies secrete hormones that stimulate the endometrial lining, occasionally there may be changes in the endometrial lining that can approximate the appearance of a gestational sac. This pseudosac will never have an inner yolk sac or fetal pole. Use of these two additional findings for defining an IUP helps ensure that the EP will not be confused. Whether scanning from a transabdominal or an endovaginal approach, all these criteria should be visualized and documented on every sonogram. The safest way to ensure that these criteria are present is a systematic approach to documenting these landmarks. In the endovaginal approach, documentation is best achieved by obtaining a single sagittal view of the gestational and yolk sacs clearly within the endometrial echo of the uterus, along with the inferiorly positioned endometrial stripe as it passes through the corpus and cervical region of the uterus (Fig. 120.3, A and B). In the transabdominal approach, documentation is best achieved by obtaining a single sagittal view of the gestational and yolk sacs clearly within the endometrial echo of the uterus, along with the anteriorly positioned bladder and the inferiorly positioned vaginal stripe (Fig. 120.4, A and B). By identifying pregnancies as intrauterine, ectopic pregnancy has effectively been excluded with reasonable certainty. There is a theoretic risk for a heterotopic pregnancy of approximately 1 in 30,000 pregnancies. When assisted reproduction is involved, the heterotopic rate is 1 in 7000 overall and as high as 1 in 900 with induction of ovulation. Even when a live IUP is identified in an assisted reproduction patient, close follow-up with the fertility specialist is recommended.

**BOX 120.3 Diagnostic Criteria**

*Intrauterine pregnancy*—Gestational sac with a concentric echogenic ring lying within the endometrial echo of the uterus that is greater than 5 mm in mean sac diameter (height, width, and length) and contains a yolk sac with or without a fetal pole

*Live intrauterine pregnancy*—Gestational sac with a concentric echogenic ring lying within the endometrial echo of the uterus that is greater than 5 mm in mean sac diameter (height, width, and length) and contains a yolk sac plus a fetal pole and cardiac activity

*Abnormal intrauterine pregnancy*—Gestational sac with a concentric echogenic ring lying within the endometrial echo of the uterus that is greater than 13 mm in mean sac diameter (height, width, and length) without a yolk sac or greater than 18 mm in mean sac diameter (height, width, and length) without a fetal pole or with an obvious fetal pole without cardiac activity

*No definitive pregnancy*—No definite gestational sac is apparent within the endometrial echo of the uterus, or if a gestational sac is visualized, it is less than 5 mm in mean sac diameter (height, width, and length)

*Extrauterine gestation: ectopic*—Gestational sac with a concentric echogenic ring lying outside the endometrial echo of the uterus that is greater than 5 mm in mean sac diameter (height, width, and length) and contains a yolk sac with or without a fetal pole and cardiac activity

**Fig. 120.3**  A and B, Endovaginal views of the sagittal plane showing an intrauterine pregnancy. The gestational sac is located within the endometrial echo of the uterus and contains a yolk sac.
LIVE INTRAUTERINE PREGNANCY

Once the pregnancy is determined to be intrauterine, the next designation is viability. This involves real-time documentation of the cardiac activity normally present at 6 weeks’ gestational age when using the endovaginal technique and at 7 to 8 weeks’ gestation when using the transabdominal technique. The criteria for documentation of a live IUP is detailed below (see Box 120.3). Simply having a fetal pole within the endometrial echo of the uterus will not suffice (Fig. 120.5, A and B). For our purposes, an IUP is not live until cardiac activity is documented. The flickering of cardiac activity is an unmistakable sign of life that can be identified by the novice sonographer and the patient as well. Documentation can be confirmed by video in B mode or by identifying the fetal heart rate by M mode (Fig. 120.6). Pulsed wave Doppler should never be used to document fetal heart rates because of the theoretic risk to the fetus of the increased heat generated by this form of ultrasound. Novice sonographers will occasionally use the zoom feature and record or print an image of a pregnancy without any definite landmarks confirming the pregnancy as intrauterine (Fig. 120.7). The problem is that ectopic pregnancies can be indistinguishable with this particular example of a cone-down view, which does not allow visualization of the landmarks that support the criteria for an IUP.

ABNORMAL INTRAUTERINE PREGNANCY

A pregnancy can be categorized as abnormal when the gestational sac is disproportionate to its contents. For example, by the time that a gestational sac measures 13 mm in diameter, a yolk sac should clearly be visualized. Likewise, by 18 mm, all intrauterine gestational sacs containing live embryos should have cardiac activity. When using conservative criteria, it is safe to conclude that any sac larger than 13 mm without a yolk sac or larger than 18 mm without evidence of cardiac activity is termed abnormal (Fig. 120.8, A and B). It has been shown in the obstetric ultrasound literature that gestational sacs reaching 13 mm in size with no yolk sac or fetal pole have virtually no viability and ultimately result in miscarriage. In most cases in which viability is equivocal, there is no rush to make a specific diagnosis (IUP versus abnormal IUP). Because these pregnancies have only a gestational sac visualized on ultrasound, obstetric consultation and close follow-up in 48 hours, repeated ultrasound, and quantitative measurement of β-human chorionic gonadotropin will be required.

EXTRAUTERINE PREGNANCY

Ectopic pregnancies represent approximately 2% of reported pregnancies, and ectopic pregnancy–related deaths account for 9% of all pregnancy-related deaths. The most common...
implantation site is within the fallopian tube (95.5%). Sites of tubal implantation in descending order of frequency are ampullary (73.3%), isthmus (12.5%), fimbrial (11.6%), and interstitial (2.6%). The remaining sites are ovarian (3.2%) and abdominal (1.3%).  
Visualization of an ectopic pregnancy on ultrasound, even for experienced sonographers, is frequently difficult. As opposed to an IUP, for which ultrasound confirms the diagnosis, an extrauterine pregnancy is often not substantiated by ultrasound and is just presumed because of the absence of an IUP or other findings of a normal pregnancy. The criteria for diagnosis of an extrauterine gestation is a gestational sac outside the endometrial echo of the uterus with evidence of a yolk sac or fetal pole (Fig. 120.9, A and B). In patients who do not have this definitive finding, the diagnosis can be made either intraoperatively or by serial ultrasound in patients who are being monitored very closely. A “ruptured”
ectopic pregnancy is frequently suspected on clinical grounds. Supportive sonographic findings of an intraperitoneal fluid collection or an adnexal mass (or both) further strengthen this suspicion. Recent literature suggests that a transabdominal approach in which a large intraperitoneal fluid collection is revealed will decrease the time to diagnosis and treatment. A pregnant female with free fluid visualized in the right upper quadrant should have these findings communicated immediately to obstetric consultants to help facilitate a shorter time to the operating room.

**NO DEFINITIVE PREGNANCY**

The diagnosis of no definitive pregnancy is established when a technically adept emergency ultrasound examination fails to diagnose an intrauterine or extrauterine gestation (Fig. 120.10, A and B). When this is encountered, three possible diagnoses exist. First, it is possible that an early IUP is present but no definitive signs are visualized within the uterus by ultrasound. Second, the products of conception may have been aborted and the empty uterus is a result of a miscarriage. Finally, a concealed ectopic pregnancy is not identified by emergency ultrasound.

Absence of proof is not proof of absence. It should be borne in mind that patients in whom no definitive pregnancy is diagnosed are at high risk for an ectopic pregnancy. The presence of free fluid in the pouch of Douglas or elsewhere in the pelvis should increase suspicion for an ectopic pregnancy substantially. The literature varies widely in defining ectopic pregnancy rates in patients with indeterminate or no definitive pregnancy. This may be due to variation in the specific criteria used to define this category. Many researchers have added subgroups such as probable ectopic pregnancy and probable IUP. The take-home message is that all patients in whom no definitive IUP is diagnosed should be managed closely with our obstetric colleagues regardless of the β-human chorionic gonadotropin level. An interdepartmental policy addressing this issue would clearly be advantageous to each specialty and the patient.

**HOW TO INCORPORATE INTO PRACTICE**

Use of bedside ultrasound for the evaluation of first trimester pregnancy is a skill that can grow with the experience and practice of the EP. Obtaining the basic skills necessary to safely and consistently identify a live IUP is an excellent foundation. This skill alone will enable EPs to discharge more than half the pregnant patients seen in the ED by identification of an IUP. The important caveat is to pay attention to detail. Identification of an IUP means finding a gestational sac within the endometrial echo of the uterus and a yolk sac or fetal pole within the gestational sac. A systematic approach should be undertaken each and every time to document the location by ultrasound landmarks (uterus, bladder, and endometrial stripe). With time, the ability to recognize abnormal IUPs and adnexal masses will grow, but the goal of EP-performed first trimester ultrasound should be to identify IUPs and refer all others for consultation and further imaging as necessary per local practice standards.

After years of providing ultrasound education, a pattern of learning is so consistent that it is worth printing to help others forgo the same mistakes. First, there is the “puzzled stage” in which everything looks like shades of gray and seems uninterpretable. The second phase is the “eureka phase” in which things start to make sense. The third phase is the most dangerous—also known as the “who’s the man (or woman)!?” phase in which overconfidence should be closely monitored and the scope of practice closely followed to prevent mistakes. Finally, in the “safe again” phase, a few tips on scanning practice are helpful. Strive to approach every patient systematically. Attempt to define the boundary of each organ that is being evaluated. Document the landmarks pertinent to each ultrasound image obtained. Discipline yourself to systematically save images that provide a clear “story” that other sonographers can follow and interpret. Always obtain confirmatory studies in cases in which the diagnosis is unclear or the images are inadequate. Finally, develop a quality assurance process to share interesting cases, provide technical and interpretative teaching points, and help avoid common errors.

11. Dart R, Kaplan B, Ortiz L. Normal intrauterine pregnancy is unlikely in emergency department patients with either menstrual days >38 days or β-hCG >3,000 mIU/mL, but without a gestational sac on ultrasonography. Acad Emerg Med 1997;4:967-71.
Preeclampsia is a disease of pregnancy characterized by a sustained elevation in blood pressure and proteinuria. Edema is common in patients with preeclampsia but is no longer considered to be necessary for the diagnosis. HELLP syndrome is a particularly severe form of preeclampsia associated with high maternal morbidity and characterized by hemolysis, elevated liver enzymes, and low platelet counts. Eclampsia is defined by seizures, usually in the setting of preeclampsia.

In patients with severe preeclampsia and eclampsia, basic management involves support of maternal vital signs, control of hypertension, prevention and treatment of seizure activity, and close consultation with obstetrics colleagues to determine the appropriate disposition.

Placental abruption and placenta previa are the most serious causes of vaginal bleeding in late pregnancy. Painful bleeding in late pregnancy is probably due to placental abruption. In contrast, when the vaginal bleeding is painless, the cause is more likely to be placenta previa.

Ultrasound evaluation of third trimester bleeding is diagnostic for placenta previa, but placental abruption is diagnosed clinically because ultrasound detects only 25% to 50% of abruptions. Treatment of third trimester bleeding includes stabilization of the patient, assessment of fetal status with ultrasound and fetal monitoring, and consultation with obstetrics colleagues to determine the need for delivery.

KEY POINTS

- Preeclampsia, a disease of the third trimester of pregnancy, is characterized by a sustained elevation in blood pressure and proteinuria. Edema is common in patients with preeclampsia but is no longer considered to be necessary for the diagnosis.
- HELLP syndrome is a particularly severe form of preeclampsia associated with high maternal morbidity and characterized by hemolysis, elevated liver enzymes, and low platelet counts.
- Eclampsia is defined by seizures, usually in the setting of preeclampsia.
- In patients with severe preeclampsia and eclampsia, basic management involves support of maternal vital signs, control of hypertension, prevention and treatment of seizure activity, and close consultation with obstetrics colleagues to determine the appropriate disposition.
- Placental abruption and placenta previa are the most serious causes of vaginal bleeding in late pregnancy.
- Painful bleeding in late pregnancy is probably due to placental abruption. In contrast, when the vaginal bleeding is painless, the cause is more likely to be placenta previa.
- Ultrasound evaluation of third trimester bleeding is diagnostic for placenta previa, but placental abruption is diagnosed clinically because ultrasound detects only 25% to 50% of abruptions.
- Treatment of third trimester bleeding includes stabilization of the patient, assessment of fetal status with ultrasound and fetal monitoring, and consultation with obstetrics colleagues to determine the need for delivery.

EPIDEMIOLOGY

Preeclampsia complicates 5% to 11% of pregnancies in the United States. The rate is higher in developing nations. This disease accounts for a significant percentage of both maternal and fetal mortality. Fetal complications such as prematurity and low birth weight are common, with death occurring in 129 of every 1000 cases. Maternal complications are common in both eclampsia and severe preeclampsia, including HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) (11%), placental abruption (10%), disseminated intravascular coagulation (DIC) (6%), neurologic deficits (6%), aspiration pneumonia (6%), pulmonary edema (5%), renal failure (4%), and death (1%).

First pregnancies are at greatest risk. Other risk factors include extremes of reproductive age, more than 10 years between pregnancies, multiple gestations, molar pregnancies, previous or family history of preeclampsia, underlying diseases (hypertension, diabetes, autoimmune or renal diseases, obesity), and thrombophilia (e.g., antiphospholipid syndrome, factor V Leiden deficiency, activated protein C resistance).

PATHOPHYSIOLOGY

Preeclampsia is a multisystem disorder of gestation. Its exact cause is unclear, and several mechanisms have been implicated. The disease is thought to originate within the placenta, which for reasons that remain obscure, has inappropriately decreased perfusion. Hypoperfusion and multiorgan effects ensue in some patients as a result of decreased intravascular volume and endothelial vascular leakage causing increased interstitial volume, interstitial protein leakage, and vasoconstriction. Preeclampsia affects nearly every organ system.
Severe preeclampsia is characterized by hypertension secondary to increased peripheral resistance. However, the profound elevation in blood pressure is the result rather than the cause of the underlying pathophysiology. Effects on the liver include edema, hepatocellular necrosis, and periportal and subcapsular hematomas. Decreased renal flow with high perfusion pressure can cause glomerular and tubular injury resulting in proteinuria or, worse, renal failure. Cerebral vasospasm leads to edema, microinfarction, and hemorrhage. Patients experience a variant of chronic DIC with thrombocytopenia and hemolysis that can worsen the already present organ system dysfunction.

HELLP syndrome is a particularly severe form of preeclampsia associated with severe maternal morbidity. Preeclampsia has long-term implications for the health of these patients. After delivery, women with preeclampsia are at increased risk for the development of chronic hypertension, cardiovascular diseases, and psychosomatic disorders.3

**PRESENTING SIGNS AND SYMPTOMS**

Classic clinical findings in patients with preeclampsia include proteinuria and an associated elevation in blood pressure; when these signs develop late in the pregnancy of a previously healthy woman, the diagnosis of preeclampsia is clear. However, preeclampsia does not always occur in such a straightforward manner. For instance, a patient with chronic hypertension complicated by chronic renal disease can be difficult to differentiate from one who has preeclampsia. Likewise, seizures in pregnant patients do not always herald eclampsia, and other structural, toxic, and metabolic causes have to be considered.

Patients may have the classic symptoms of severe preeclampsia, such as seizures superimposed on hypertension and proteinuria, or may have incidentally noted hypertension and proteinuria with or without edema. Persistent elevation in blood pressure is the hallmark of preeclampsia. Hypertension is defined as a sitting blood pressure of 140 mm Hg systolic or 90 mm Hg diastolic or greater. Blood pressure readings should ideally be taken more than 6 hours apart; however, for most patients in the emergency department (ED), if concern is high, therapy should not be delayed. Early in pregnancy, diastolic blood pressure decreases but returns to normal toward the 28th week of gestation. Therefore, a sustained diastolic blood pressure of greater than 90 mm Hg at the midpoint of pregnancy should be considered elevated unless the patient has a clearly documented history of hypertension.

If the patient’s blood pressure before pregnancy is known, an increase in systolic blood pressure of 30 mm Hg or greater and an increase in diastolic blood pressure of 15 mm Hg or greater are diagnostic of preeclampsia. In addition to hypertension, the patient will have proteinuria of 1+ or greater on urinalysis.

Patients with severe preeclampsia may have additional symptoms of organ involvement (Box 121.1), including significant edema, especially facial edema, and documented weight gain of more than 5 pounds per week. Findings ominous for severe preeclampsia include a blood pressure of 160 mm Hg systolic and 110 mm Hg diastolic or greater, visual disturbances (blurred vision or scotomata), severe headache, altered mental status, seizures (which defines eclampsia), hyperreflexia with clonus, severe epigastric or right upper quadrant pain on examination, retinal hemorrhage with exudates and papilledema (which is rare and more commonly indicates underlying chronic hypertension), bilabial rales and evidence of frank pulmonary edema, oliguria, and petechiae and bleeding from puncture sites.

Fetal growth retardation and oligohydramnios may be seen in cases of severe preeclampsia, but this information is not usually available. Sudden onset of abdominal pain with a firm painful uterus suggests placental abruption, which complicates up to 10% of preeclamptic pregnancies.

**BOX 121.1 Clinical Manifestations of Severe Preeclampsia**

**Cardiovascular**
- Increased cardiac output, systemic vasoconstriction, systemic hypertension, increased hydrostatic pressure, generalized edema

**Obstetric**
- Uteroplacental insufficiency, fetal growth retardation, fetal hypoxemia and distress, decidual ischemia or thrombosis, placental abruption, placental infarcts

**Renal**
- Decreased renal blood flow and glomerular filtration rate, endothelial damage, proteinuria, elevated creatinine levels and decreased creatinine clearance, oliguria, elevated uric acid levels, renal tubular necrosis, renal failure

**Hematologic**
- Intravascular hemolysis (schistocytes, burr cells, elevated free hemoglobin and iron, decreased haptoglobin levels), thrombocytopenia, disseminated intravascular coagulation (increased fibrin split products, decreased fibrinogen)

**Cerebrovascular**
- Ischemia, generalized grand mal seizures (eclampsia), high cerebral perfusion pressure with regional ischemia, cerebral hemorrhage, cerebral edema, coma, central blindness, loss of speech

**Hepatic**
- Ischemia, hepatic cellular injury, elevated liver enzymes, mitochondrial injury, intracellular fatty deposits

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The current classification of hypertension in pregnancy is divided into four categories: preeclampsia, gestational or transient hypertension, chronic hypertension, and preeclampsia superimposed on chronic hypertension (Box 121.2). In addition, occult renal disease can be manifested as proteinuria and associated hypertension.

The differential diagnosis of severe preeclampsia is broad and distinction may be difficult, particularly with concomitant HELLP syndrome.6 Thrombotic thrombocytopenic purpura (TTP) and preeclampsia can have identical findings.
of thrombocytopenia, hemolytic anemia, renal disease, and neurologic abnormalities. In patients with preeclampsia, the hypertension, proteinuria, and edema tend to precede the hematologic abnormalities. However, by the time that the patient arrives in the ED, these subtle distinctions may be almost impossible to delineate.

Laboratory tests may help clarify the diagnosis and determine the severity of the preeclampsia. If proteinuria is 1+ or greater on urinalysis, a hypertensive pregnant woman should be considered to have preeclampsia unless proved otherwise. A 24-hour urine collection is more sensitive for this purpose, but its use is not realistic in the ED.

A complete blood count should be performed with a manual differential and haptoglobin assay to evaluate for hemolysis. Decreased platelet counts (<100,000/mm³) are associated with severe disease. Fibrinogen levels, fibrin split products, and a prothrombin time (PT) and partial thromboplastin time (PTT) should be ordered to evaluate for DIC, which may complicate severe preeclampsia.

A comprehensive metabolic profile should be obtained because elevated serum creatinine, especially when associated with oliguria, and elevated liver transaminases suggest severe preeclampsia. Uric acid levels should be assessed; the degree of elevation of uric acid has been shown to correlate with the severity of the preeclampsia. Elevated lactate dehydrogenase (LDH) levels indicate hemolysis but can also be a result of liver involvement. Typing plus crossmatching of blood is necessary in cases of severe preeclampsia or anticipated delivery.

HELLP syndrome is characterized by peripheral smears showing schistocytes and burr cells, elevated LDH levels (>600 U/L), elevated liver enzymes (bilirubin > 1.2 and aspartate transaminase > 70 U/L), and low platelet count (<100,000). In addition, the abnormal laboratory test results in patients with HELLP syndrome can be seen in the other diseases noted in Box 121.3.

Table 121.1 shows the frequency of certain signs and laboratory values that may help distinguish between several of the key conditions that mimic severe preeclampsia with HELLP syndrome.

TREATMENT

It is important to differentiate between mild and severe preeclampsia when discussing the patient with the obstetrics consultant because acute management depends on the severity of disease, as well as fetal maturity. Recent research favors delivery over observation for gestational age older than 36 weeks.

In patients with severe preeclampsia and eclampsia, basic management involves the following measures: (1) support of

---

**BOX 121.2 Classification of Hypertension in Pregnancy**

- **Preeclampsia and Eclampsia**
  - Hypertension and proteinuria detected for the first time after the 20th week of gestation
  - Eclampsia is the occurrence of seizures in a patient with preeclampsia

- **Gestational or Transient Hypertension**
  - Hypertension without proteinuria after the 20th week of gestation (resolves within 3 months of delivery)

- **Chronic Hypertension**
  - Hypertension diagnosed before the 20th week of gestation or before the pregnancy

- **Preeclampsia Superimposed on Chronic Hypertension**
  - Development of accelerated hypertension or proteinuria after the 20th week of gestation in a patient with hypertension diagnosed before the 20th week or before the pregnancy

---

**RED FLAGS**

**Preeclampsia and Eclampsia**

Pain with a firm, painful uterus suggests placental abruption, which is a complication in up to 10% of preeclamptic pregnancies.

Diagnosing preeclampsia may be difficult in patients with chronic hypertension complicated by chronic renal disease.

Seizures in pregnant patients do not always herald eclampsia, and other structural, toxic, and metabolic causes should be considered.

Both thrombotic thrombocytopenic purpura and preeclampsia can have the identical findings of thrombocytopenia, hemolytic anemia, renal disease, and neurologic abnormalities. In patients with preeclampsia, the hypertension, proteinuria, and edema tend to precede the hematologic findings, and in patients with thrombotic thrombocytopenic purpura, they generally follow and are a result of the hematologic abnormalities.

---

**DOCUMENTATION**

**Preeclampsia and Eclampsia**

Pregnant women being evaluated should have their blood pressure documented; any elevation needs to be addressed. A complete history should include symptoms (e.g., headache, vision changes, abdominal pain) identifying causes of the elevation.

Review of records may indicate that the elevation is chronic and that the patient is being monitored for this finding.

If the blood pressure is not dangerously high and no other evidence of preeclampsia is present, it may be addressed by making arrangements for close outpatient follow-up.

Documentation should include completion of appropriate laboratory testing.

Patients with severe preeclampsia and eclampsia require documentation of all actions taken, interventions given, consultations requested, and the time at which all were ordered.
maternal vital functions and initiation of laboratory test evaluation, (2) control of severe hypertension, (3) prevention and treatment of seizures, and (4) early consultation for determination of final treatment (capability of the hospital to deliver maternal and fetal care, decision regarding immediate delivery).10

The patient should be placed in the left lateral decubitus position with large-bore intravenous (IV) access; however, large fluid boluses should be avoided. Patients should receive supplemental oxygen and, if the airway is in danger of compromise, should be intubated, with attempts to minimize elevations in intracranial pressure. Vital signs should be monitored continuously. Fever may indicate infection, may mean that the patient has a disorder other than preeclampsia (e.g., acute fatty liver of pregnancy, TTP), or may be the result of prolonged seizures. As the maternal condition is stabilized, fetal heart rate monitoring should begin.

In preeclamptic patients, the mainstay of treatment is administration of magnesium for seizure prophylaxis when diastolic
blood pressure exceeds 100 mm Hg. Magnesium is superior to phenytoin (Dilantin) or diazepam for prevention of eclamptic seizures.\textsuperscript{11} The recommended dosage is 4 to 6 g of magnesium administered intravenously over a 15-minute period, followed by a maintenance infusion of 1 to 2 g/hr, with a goal of serum levels of 4 to 6 mEq/L. The maintenance dosing should be started only if the patient still has patellar reflexes and an adequate respiratory rate. Magnesium should be used cautiously in patients with renal insufficiency or oliguria. When systolic blood pressure reaches 160 mm Hg or diastolic pressure reaches 105 mm Hg, most experts recommend the use of an antihypertensive agent. The ideal antihypertensive agent for preeclampsia is one that reduces blood pressure in a controlled manner and has minimal side effects (Table 121.3).\textsuperscript{12,13} The exact degree of reduction is controversial, but it is reasonable to maintain diastolic blood pressure between 90 and 110 mm Hg.

Hydralazine hydrochloride (Apresoline) has been commonly used as an antihypertensive agent for patients with severe preeclampsia. Its mechanism of action is through direct relaxation of arteriolar smooth muscle. This drug can be given as 5- to 10-mg boluses every 15 to 20 minutes until a response in blood pressure is seen. Side effects include tachycardia, nausea, vomiting, headache, and epigastric pain.

Labetalol, a combination $\alpha$- and $\beta$-adrenergic blocking agent, is another commonly used medication, and some authors prefer this agent over hydralazine.\textsuperscript{14} The dose is 20 to 40 mg administered as a slow IV push every 20 minutes. This can be followed by 1 to 2 mg/min given by continuous infusion or by IV dosing every 3 hours after the blood pressure has been controlled. Side effects include flushing, orthostatic hypotension, and tremulousness. Labetalol should not be used in patients with asthma or evidence of heart failure.

Antihypertensive agents to use with caution, if at all, include nifedipine and nitroglycerin. Calcium channel blockers such as nifedipine (10 mg orally every 30 minutes) have been used for refractory cases of hypertension. However, there is concern about a precipitous decrease in blood pressure when magnesium and nifedipine are used together. Nitroglycerin, a venous (predominantly) and arterial vasodilator, has also been used for refractory cases of hypertension, particularly if the patient has evidence of congestive heart failure resulting from the hypertension. However, when high doses are used, the patient should be monitored for the development of methemoglobinemia.

Other antihypertensive agents to avoid include sodium nitroprusside and angiotensin-converting enzyme inhibitors. Sodium nitroprusside should be used only as a last resort because fetal cyanide poisoning has been reported in animal studies.\textsuperscript{15} However, if the blood pressure is not responding to other agents, use of this medication is appropriate. Angiotensin-converting enzyme inhibitors have been shown to cause fetal death in animals and possibly renal failure in neonates and thus should not be used in pregnancy. Clonidine and $\alpha$-methyldopa are not administered parenterally and are therefore rarely used in initial management of preeclampsia.

The treatment of eclampsia and severe preeclampsia is delivery. The method of delivery (cesarean or vaginal) depends on gestational age, cervical maturation, and clinical status. In patients with less than 32 weeks’ gestation and mild preeclampsia, care is controversial and detailed discussion with an obstetrician is needed. If a decision is made to observe the patient, low-dose aspirin is sometimes recommended. Blood typing and crossmatching should be ordered if the severity of illness indicates the need for delivery.

Treatment of specific complications of preeclampsia includes dexamethasone, which may be useful in patients with HELLP syndrome. However, this is therapy is not yet universally accepted and consultation is recommended. Betamethasone, which will accelerate fetal lung maturity after 24 hours, may also be considered. DIC should be treated with replacement of blood products and coagulation factors as indicated clinically; however, heparin is not usually recommended. Epidural anesthesia in the setting of DIC or thrombocytopenia may be contraindicated because of the risk for epidural hematoma.

In pregnant women evaluated in the ED for any complaint, blood pressure should be considered carefully. Mild preeclampsia may progress rapidly to severe preeclampsia with
little warning. If a pregnant patient is found to have elevated blood pressure, the initial assessment should include a complete history and physical examination with attempts to determine whether the elevated blood pressure is new or old and whether other evidence of preeclampsia is present (Fig. 121.1). If there is concern that the elevated blood pressure indicates preeclampsia, the patient will usually need admission for close monitoring and therapy.

Patients with preeclampsia and eclampsia will need emergency obstetrics consultation to assist in management and admission versus transfer decisions.

**THIRD TRIMESTER BLEEDING**

**EPIDEMIOLOGY**

Vaginal bleeding occurs in about 3% to 4% of second and third trimester pregnancies. It can herald catastrophic problems for both the mother and fetus. Placental abruption and placenta previa are the most serious causes of vaginal bleeding in late pregnancy. In 20% of women the bleeding is due to placenta previa, and in 33% it is due to placental abruption.
Placental abruption is estimated to occur in about 1% of all pregnancies. Of these pregnancies, 20% to 40% will be associated with perinatal morbidity or mortality involving the mother or fetus. Maternal death, though diminishing in incidence (0.03% of pregnant women), remains significant. Additionally, women who sustain trauma in pregnancy are at risk for abruption, even when the trauma appears to be minimal.

Ultrasound studies estimate that the incidence of placenta previa is higher (about 5%) in the second trimester. The incidence decreases to about 0.5% of pregnancies at delivery as the uterus enlarges and pulls the placenta away from the cervical os.

Vaginal bleeding in late pregnancy has causes other than placenta previa or placental abruption (e.g., cervical and vaginal abrasions or polyps) in about 50% of patients; nonetheless, these women need close follow-up. The risk for second trimester miscarriage or perinatal morbidity is as high as 30% in this group. Investigation of other causes of vaginal bleeding should be delayed until the diagnosis of placenta previa or placental abruption is ruled out. Vaginal bleeding in all patients should receive serious consideration, even if the bleeding appears to be self-limited.

**PATHOPHYSIOLOGY**

**PLACENTAL ABRUPTION**

Placental abruption, or abruptio placentae in Latin (meaning “rending asunder of the placenta”), is premature separation of the normally implanted placenta from the uterine decidua lining. Initially, there is bleeding into the placental decidua basalis, a thin layer adherent to the myometrium, and then bleeding into the abruption placental tissue. The pathophysiology causing the initial bleeding is not clearly understood in many cases. The blood creates a potential space and can track to the cervix and cause vaginal bleeding. The margin, part, or all of the placenta may separate and result in minimal to a large amount of bleeding. Women will bleed vaginally with revealed abruption, or the blood may be contained behind the placenta with concealed abruption. It can also disrupt the placenta and result in bloody amniotic fluid.

The vascular placental bed can bleed significantly and cause maternal hypotension. Loss of the placental circulation may cause fetal distress or death because the hematoma between the layers prevents that area of placenta from exchanging nutrients and oxygen. In addition, significant uterine spasm is typically present. The combination of spasm and decreased perfusion causes the fetus to become hypoxic. Fetal bleeding can occur but is more likely with traumatic placental abruption. The hallmark of placental abruption is vaginal bleeding and uterine tenderness.

Risk factors for placental abruption include previous placental abruption, cocaine use, smoking, hypertension in pregnancy (preeclampsia, gestational or chronic hypertension), trauma, advanced maternal age, multiparity, and multiple gestation. Other risk factors are fetal malformation, premature rupture of membranes, uterine leiomyomas, previous cesarean section, and malnutrition.

Hypertension increases not only the risk for placental abruption but also the risk for more severe placental abruption and increased fetal mortality. Elevations in blood pressure may predispose the placenta to bleeding, but the exact initiating event is still elusive.

Major trauma, as well as seemingly insignificant trauma, is an important cause of placental abruption. Because pregnant trauma patients are initially managed in the ED, the emergency physician should be vigilant for signs of placental abruption. Abruption may be seen in up to 30% of patients with severe abdominal trauma and in up to 3% with minor trauma in late pregnancy.

Additional complications of placental abruption include maternal morbidity, massive blood loss, renal failure, fetal mortality, preterm birth, and low birth weight. Coagulopathy and progression to DIC may develop, and the cause is multifactorial. The larger the abruption, the more likely DIC is to develop because clot serves as a nidus for activation of the intrinsic and extrinsic pathways of coagulation. Another mechanism for the development of DIC is the loss of endothelial integrity; exposure of thromboplastin stimulates the coagulation cascade.

**PLACENTA PREVIA**

Painful bleeding in late pregnancy is probably due to placental abruption; however, when the vaginal bleeding is painless, the cause is more likely to be placenta previa, with the placenta being located either partially or completely over the cervical os. In preparation for labor, softening of the lower uterine segment and effacement of the cervix tear the implanted placenta previa, which results in painless vaginal bleeding. Only 10% of women have contractions or uterine tenderness coincident with the initial vaginal bleeding. Many women have brief painless bleeding initially, which is a warning that placenta previa is present. As the cervix dilates further, the bleeding can become rapid and life-threatening.

Placenta previa can be total, partial, marginal, or low lying. The exact cause of placenta previa is unclear, but it is thought that factors that decrease the richness of the vascular bed of the uterus (defective decidual vascularization) or “scar” the uterus predispose to placental implantation in the lower uterine segment and cervix. The risk for placenta previa is increased with previous cesarean section and advanced maternal age. Other risk factors include previous placenta previa, assisted reproduction, cocaine use, and smoking. The presence of multiple implantation sites in multiparous women and multiple gestations also increases the risk. In addition, the placenta often preferentially implants near the scar of a previous cesarean section but then expands to cover the cervix as well. It is uncertain whether the lower uterine scar prevents the normal elongation of the lower uterine segment that would normally pull the placenta away from the cervix or whether the uterus is not rich enough to support the placenta, which causes it to enlarge and cover the cervix. Whatever the cause, the eventual vaginal bleeding is caused by softening of the lower uterine segment and subsequent disruption of the placental attachment.

Although placenta previa may be diagnosed in the second trimester, in many women, as the uterus enlarges, it pulls the placenta away from the cervix, thereby eliminating the previa; in this manner 90% of cases of placenta previa diagnosed before the 20th week of gestation resolve. Therefore, definitive diagnosis of placenta previa is made after the 24th week of gestation.
PRESENTING SIGNS AND SYMPTOMS

In women with late pregnancy bleeding, there are three key historical points: painful or painless bleeding, volume of bleeding, and presence of fetal movement. The classic manifestation of placental abruption is painful vaginal bleeding associated with fetal distress. However, the clinical findings of abruption vary from asymptomatic to significant painful bleeding to catastrophic maternal or fetal death. Most women have uterine contractions, and about one third have uterine hypertonus. Symptoms may also include back pain when the placental location is posterior. Fetal distress may be noted from lack of movement and fetal heart rate patterns that include fetal decelerations, reduced variability, and bradycardia. In the majority of cases the abruption is not due to trauma; however, in the ED population, trauma is an important cause. The shearing force of minor trauma such as a fall or motor vehicle crash might initiate abruption.

In contrast to placental abruption, the classic finding in patients with placenta previa is painless bleeding. The bleeding varies from mild to massive and from intermittent to continuous. Bleeding usually occurs after the 28th week of gestation.

Vaginal bleeding past the first trimester of pregnancy is abnormal and should be taken seriously. The patient’s obstetric history, as well as social and medical history, may contribute to the diagnosis and alert the physician to complicating factors. The onset, duration, and quantity of vaginal bleeding are relevant to determine the patient’s stability; trauma and sexual activity may stimulate bleeding. Bleeding after trauma is more likely to be due to placental abruption, whereas intercourse may provoke bleeding from placenta previa.

The duration of bleeding, estimated volume of blood lost, and number of pads used can help determine the volume of blood loss. A typical saturated pad holds about 30 mL of blood. Because several liters of blood can remain concealed in the uterus, it is easy to underestimate the volume of blood lost.

During the initial evaluation, women should be asked whether they felt any fetal movements in the past few hours. Lack of movement may indicate fetal death or compromise.

The physical examination should not include speculum or manual pelvic examination as part of the evaluation of patients with third trimester bleeding. In the presence of placenta previa, cervical manipulation may cause torrential vaginal bleeding. If the patient has had second trimester ultrasound performed with no placenta previa documented, internal examination may be performed.

The evaluation should include fundal height measurement and evidence of uterine tenderness, contractions, or a hypertonic uterus. Severe placental abruption causes uterine irritability manifested as frequent contractions with increased baseline tone (high-frequency contractions). In patients with placenta previa, the uterus should be soft, although 10% of these patients may be in labor and have contractions that should not be confused with the uterine irritability of placental abruption. Fetal descent into the pelvis should be noted, and the presenting part may be determined with Leopold maneuvers.

In cases of vaginal bleeding caused by trauma, placental abruption is highest on the list of differential diagnoses. However, if the pain is caused by trauma to other organs, the bleeding might be due to placenta previa. In about 10% of cases, abdominal pain occurs with placenta previa. The pain may be due to the bleeding or the onset of labor.

Although vaginal bleeding occurs in 80% of cases of placental abruption, some abruptions are concealed without any evidence of overt bleeding, thereby making diagnosis difficult. It is thus important to realize that abruption may be accompanied by symptoms that can be either minor or severe (shock, fetal demise, tetanic contractions).

TIPS AND TRICKS

Third Trimester Bleeding
Do not perform a speculum examination in patients with third trimester bleeding.
Major trauma, as well as seemingly insignificant trauma, is an important cause of placental abruption.
All vaginal bleeding during the third trimester should be considered serious; investigation for other causes of the vaginal bleeding should be delayed until the diagnosis of placenta previa or placental abruption is ruled out.
Focus on maternal stabilization—when mom does well, the fetus has a better chance to do well.
Diagnosis of placental abruption is based on clinical signs; the diagnosis should always be considered in pregnant women seen in the ED with significant uterine contractions and fetal distress.

Placental Abruption
Painful vaginal bleeding
Concealed abruption is difficult to diagnose
Uterine contractions
More likely after trauma

Placenta Previa
Painless vaginal bleeding
Usually occurs after the 28th week of gestation
Uterine irritation not present
Bleeding more likely to start after sexual intercourse

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Uterine rupture is a rare but catastrophic event that should be considered in the differential diagnosis of placental abruption. It is most commonly seen in women with previous cesarean section or after severe trauma. Fetal mortality is close to 100%, and maternal mortality is significant. Bleeding may or may not be present, but there is usually severe abdominal pain and a rigid gravid abdomen. The diagnosis is made operatively or by ultrasonography. With trauma, other injuries such as liver or splenic lacerations need to be considered and ruled out.

The maternal response to volume depletion is to decrease blood flow to nonvital organs, including the uterus, with resultant fetal hypoxia manifested as bradycardia with a fetal heart rate lower than 100 beats/min. Bradycardia and fetal distress may have a variety of causes and may be present in placental abruption without maternal compromise. In addition, it should
be noted that up to 20% of cases of placental abruption are initially manifested as fetal demise.

Following clinical examination, ultrasound imaging may be performed, which may result in another diagnosis in 25% to 50% of cases (Box 121.4). About 10% of pregnant patients with abdominal pain and bleeding may have preterm labor, heavy bloody show with the onset of labor, or marginal placental or subchorionic bleeding. These patients should be admitted for monitoring. Other causes of vaginal bleeding are vaginal or cervical polyps, cervical lacerations or erosions, cervical carcinoma, and vulvar injury.

Patients in the second half of pregnancy with abdominal or back pain but without vaginal bleeding should first be considered to have placental abruption because concealed hemorrhage is present in 10% of placental abruptions. Other causes of abdominal pain should also be considered, such as pyelonephritis, nephrolithiasis, appendicitis, ovarian torsion, and other abdominal processes. Abnormal laboratory findings such as blood in the urine and an elevated white blood cell count may help in the differential diagnosis.

### Differential Diagnosis of Third Trimester Bleeding
